RE: CCR Alternative Liner Application

Dear Mr. Wheeler:

Great River Energy is submitting the attached Alternative Liner Application for the Upstream Raise 91 CCR surface impoundment at Coal Creek Station. This application was prepared in response to the requirements at 40 CFR 257.71(d)(1).

Should you have any questions regarding the attached report, please contact Shane Stockdill at 701-442-7010 or sstockdill@grenergy.com or Erik Heinen at 612.801.1269 or eheinen@grenergy.com.

Sincerely,

GREAT RIVER ENERGY

Greg Archer
Manager, Environmental Services

Executive Summary

Golder Associates Inc. (Golder) has prepared this application in support of submitting an alternative liner demonstration for the Upstream Raise 91 coal combustion residual (CCR) surface impoundment (Upstream Raise 91) at Great River Energy's (GRE's) Coal Creek Station (CCS). This application includes a discussion of background information regarding the existing CCR facility, documentation regarding the design and construction of the liner system, documentation of current facility compliance with the CCR Rule, and information regarding the current groundwater monitoring system network and statistical results for Upstream Raise 91.

A summary of CCR Rule requirements for this application and where they are addressed in this application is found in Table ES-1.

Table ES-1: Summary of Application Information

CCR Rule Citation 40 CFR Part 257	Information Requested	Where Addressed in this Demonstration
71(d)(1)(i)	Letter to the Administrator or the Participating State Director, announcing their intention to submit a demonstration under paragraph (d)(1)(ii) of this section, including the location and specific CCR surface impoundment for which the demonstration will be made.	Cover letter
71(d)(1)(i)(A)	A certification signed by the owner or operator that the CCR unit is in full compliance with 40 CFR 257 except for 257.71(a)(1).	Appendix A-1
71(d)(1)(i)(B)(1)	Documentation that the groundwater monitoring network meets all the requirements of 40 CFR 257.91.	Section 4.0 and Appendix B
71(d)(1)(i)(B)(1)(i)	Map(s) of groundwater monitoring well locations in relation to the CCR unit(s) that depict the elevation of the potentiometric surface and the direction(s) of groundwater flow across the site;	Figures 5, 6, and 7
71(d)(1)(i)(B)(1)(ii)	Well construction diagrams and drilling logs for all groundwater monitoring wells;	Appendix B-7
71(d)(1)(i)(B)(1)(iii)	Maps that characterize the direction of groundwater flow accounting for temporal variations;	Figures 5, 6, and 7
71(d)(1)(i)(B)(1)(iv)	Any other data and analyses the owner or operator of the CCR surface impoundment relied upon when determining the design and location of the groundwater monitoring network.	Section 4.3 and Appendix B-3, Appendix B-4, Appendix B-5, and Appendix B-6,

CCR Rule Citation 40 CFR Part 257	Information Requested	Where Addressed in this Demonstration
71(d)(1)(i)(B)(2)	Documentation that the CCR surface impoundment remains in detection monitoring.	Section 5.0 and Appendix C
71(d)(1)(i)(B)(3)	Documentation that the unit meets all the location restrictions under 40 CFR 257.60 through 257.64.	Section 3.2 and Appendix A-2
71(d)(1)(i)(B)(4)	The most recent structural stability assessment required at 40 CFR 257.73(d).	Appendix A-3
71(d)(1)(i)(B)(5)	The most recent safety factor assessment required at 40 CFR 257.73(e).	Appendix A-3
71(d)(1)(i)(C)	Documentation of the design specifications for any engineered liner components and supporting data.	Section 6.0 and Appendix D
71(d)(1)(i)(D)	A demonstration that there is no reasonable probability that a complete and direct transport pathway (i.e., not mediated by groundwater) can exist between the impoundment and any nearby water body.	Section 7.0

GRE manages CCR in three CCR surface impoundments and one CCR landfill at CCS (Figure ES-1). These CCR surface impoundments and CCR landfill are regulated by the CCR Rule and are also permitted and regulated by the North Dakota Department of Environmental Quality (NDDEQ). Upstream Raise 91 and Upstream Raise 92 both operate as CCR surface impoundments and will be closed with CCR in-place. The Drains Pond System is currently being used to dewater bottom ash and as a process water impoundment that is used to return conveyance water back to the plant. Southeast 16 operates as a landfill and is used as a storage/disposal facility for CCRs that do not contain free liquid. This application to submit an alternative liner demonstration is only focused on Upstream Raise 91.

Figure ES-1: Coal Creek Station Coal Combustion Residual Facilities

Upstream Raise 91 was constructed as an above-grade impoundment with soil embankments and a composite liner system in 1992. The Upstream Raise 91 composite liner system was constructed with an upper component consisting of high-density polyethylene (HDPE) geomembrane having a minimum thickness of 40 mils and a lower component consisting of a compacted soil layer at least two feet thick with a hydraulic conductivity less than $1x10^{-7}$ centimeters per second (cm/sec). Construction Quality Assurance (CQA) monitoring was performed during installation of the Upstream Raise 91 composite liner system in 1992. Both the low-permeability soil layer and geomembrane layer were monitored as part of the CQA monitoring effort and confirmed the integrity and longevity of the 40-mil HDPE geomembrane materials and the capability to produce quality welded seams, even 20 years or more after the 40-mil geomembrane was originally installed. In fact, as outlined in this application, the geomembrane strength information appears comparable to, and in most cases higher than, those required for 60-mil HDPE field seams under current industry standards. In addition, several evaluations by industry experts have been performed comparing the performance of the CCR rule prescriptive composite liner with alternative composite liners like Upstream Raise 91 with its thinner geomembrane layer. Conclusions from these reports indicate hydraulic flux through alternative composite liner systems similar to that of Upstream Raise 91 are comparable to the prescriptive liner system.

Due to the upstream raise design, distance from the facility to the adjacent water body (Samuelson Slough), groundwater monitoring system, and existing composite liner system, no reasonable probability exists for a sub-surface water release from the facility not mediated by groundwater.

A monitoring well network meeting the requirements of 40 CFR 257.91 has been used to monitor the groundwater upgradient and downgradient of Upstream Raise 91. Detailed information is included to describe the hydrogeologic conditions to support the vertical placement of the monitoring well screens and spatial conditions

surrounding the monitoring well network. As a part of the evaluation, vertical gradients were reviewed and concluded that an upward gradient generally exists on site, which would indicate that the wells, which are placed in the uppermost water bearing zone are appropriately placed to monitor potential releases from the facility. In addition, historic documentation, including previous groundwater monitoring plans and documentation reviewed and approved by the NDDEQ indicate the well network at Upstream Raise 91 is adequate.

Intra-well statistics (comparing compliance data to baseline data within a single well) was identified as an appropriate method for groundwater detection monitoring for Upstream Raise 91. This conclusion is based on an evaluation of the spatial variability within the monitoring network as evidenced by geochemical information, as well as ongoing observations from the historical impacts as demonstrated through hydrogeological travel time calculations and comparisons between historic and recent geochemical conditions. At present, the groundwater monitoring system for Upstream Raise 91 remains in detection monitoring, as defined by 40 CFR 257.94. As such, groundwater at the facilities is monitored on a semi-annual basis for the parameters listed in Appendix III of the CCR Rule. Assessment monitoring as defined in 40 CFR 257.95 has not been initiated. Groundwater Protection Standards (GWPS) have not been formally developed as described in 40 CFR 257.95(d)(2) and 40 CFR 257.95(h) due to the program remaining in detection monitoring. Additional analysis of groundwater monitoring data has been performed as a part of this application to support the groundwater monitoring program conclusions, including a comparison to alternate statistical methods and a preliminary review of parameters listed in Appendix IV of the CCR Rule.

As required by the alternative liner application, Upstream Raise 91 has also maintained compliance with all CCR Rule requirements as specified in 40 CFR part 257 subpart D (see Section 3.0). Information that supports compliance with CCR Rule requirements includes:

- Owner's Certification of Compliance – 257.71(d)(1)(i)(A)
- Location Restrictions – 257.71(d)(1)(i)(B)(3)
- Structural Stability and Safety Factor Assessment - 257.71(d)(1)(i)(B)(4) and 257.71(d)(1)(i)(B)(5)

Additional documents pertaining to CCR requirements that are not included as part of this application are accessible on GRE's publicly accessible CCR website, located at: https://ccr.greatriverenergy.com/.

1.0 INTRODUCTION

Golder Associates Inc. (Golder) has prepared this application in support of submitting an alternative liner demonstration for the Upstream Raise 91 coal combustion residual (CCR) surface impoundment (Upstream Raise 91) at Great River Energy's (GRE's) Coal Creek Station (CCS). Coal Creek Station is a 1,200-megawatt coal-fired electric generation facility owned and operated by GRE, located in McLean County, approximately 10 miles northwest of Washburn, North Dakota. Upstream Raise 91 is located in the south-central portion of the plant site east of the plant buildings (Figure 1). Upstream Raise 91 operates as a CCR surface impoundment and will eventually be closed with CCR in-place. The facility is used as a combined dewatering and storage facility for CCR including fly ash, bottom ash, economizer ash, and flue gas desulfurization (FGD) material.

This application includes documentation to support an alternative liner demonstration and has been prepared in response to the requirements previously promulgated in April 2015 under Title 40 of the Code of Federal Regulations (40 CFR) Part 257 (the CCR Rule, USEPA 2015) as well as in the rule revision entitled "A Holistic Approach to Closure Part B: Alternate Demonstration for Unlined Surface Impoundments," which was entered onto the Federal Register on November 12, 2020 (USEPA 2020b).

This application includes a discussion of background information regarding the existing CCR facility, documentation regarding the design and construction of the liner system, documentation of current facility compliance with the CCR Rule, and information regarding the current groundwater monitoring system network and statistical results for Upstream Raise 91.

A summary of CCR Rule requirements for this application and where they are addressed in this application is found in Table 1.

2.0 BACKGROUND

GRE manages CCR in three CCR surface impoundments and one CCR landfill at CCS. The location of each CCR management facility is shown on Figure 1. These CCR surface impoundments and landfill are regulated by the CCR Rule and are permitted and regulated by the North Dakota Department of Environmental Quality (NDDEQ). The four facilities are:

- Southeast Section 16 CCR Landfill (Southeast 16)
- Drains Pond System CCR Surface Impoundment (Drains Pond System)
- Upstream Raise 91 CCR Surface Impoundment (Upstream Raise 91)

- Upstream Raise 92 CCR Surface Impoundment (Upstream Raise 92)

Upstream Raise 91 and Upstream Raise 92 both operate as CCR surface impoundments and will be closed with CCR in-place. The Drains Pond System is currently being used to dewater bottom ash and as a process water impoundment that is used to return conveyance water back to the plant. Southeast 16 operates as a landfill and is used as a storage/disposal facility for CCRs that do not contain free liquid. This application to submit an alternative liner demonstration is only focused on Upstream Raise 91.

2.1 CCR Management at CCS

To provide an overview of how CCR and related materials are managed at the facility, a simplified process flow diagram for CCR and non-CCR material management at CCS is shown in Figure 2. GRE produces approximately 1.1 million cubic yards (cy) of CCR and non-CCR every year. Of this material, approximately 300 to 400 thousand cy of CCR per year (predominantly fly ash) is beneficially used offsite, and approximately 700 to 800 thousand cy of CCRs and non-CCR waste per year is deposited into the four CCR facilities described above.

- Bottom ash, economizer ash, and pulverizer rejects (referred to collectively as bottom ash throughout this document) are collected wet in the plant and hydraulically transported to the Drains Pond System (west cell) where the material is allowed to dewater and then hauled and deposited primarily to either Upstream Raise 91 or Upstream Raise 92, with some material being placed at Southeast 16.
- Fly ash is handled dry with most of the fly ash produced at CCS being beneficially used offsite. CCS also receives CCR from GRE's Spiritwood Station, which is a product having similar physical characteristics to CCS fly ash. Since the amount of CCR from Spiritwood Station is relatively small compared with the quantity of fly ash produced at CCS and the materials have similar characteristics, mention of fly ash in the remainder of this document refers to the combined CCS fly ash and Spiritwood Station ash. Most of the fly ash not beneficially used offsite is used in construction of the fly ash shell of Upstream Raise 91 and Upstream Raise 92.
- FGD material is a wet product and is hydraulically transported to either Upstream Raise 91 or Upstream Raise 92.
- Air jig rejects (non-CCR waste) are collected dry and are temporarily stored in a silo north of the main plant buildings prior to being loaded into haul trucks for transport to permitted containment facilities. Upstream Raise 91, Upstream Raise 92, and Southeast 16 are permitted to receive air jig rejects via NDDEQ permits. Air jig rejects are occasionally used to supplement bottom ash within Upstream Raise 91 and Upstream Raise 92 since the material has similar desirable physical properties to that of the bottom ash. However, a majority of the air jig rejects are hauled for placement in Southeast 16.

2.2 Upstream Raise 91 Site History

CCRs were originally managed in the South Ash Pond, which is a legacy facility at CCS. The South Ash Pond CCR and process water containment area was made by constructing a clay core dike around the perimeter and relying on in-situ low permeability soil to act as a soil liner across the floor. This facility was put into operation in 1979 and operated intermittently from 1979 through 1990. Due to the identification of groundwater impacts, the South Ash Pond was removed from service in 1990. In the early 1990s, as part of the site corrective action to address the groundwater impacts, the South Ash Pond was closed by removal of CCRs. In-place CCRs and a portion of the underlying subsoil were excavated from the South Ash Pond and transported to an offsite landfill. After CCRs were cleaned out of the South Ash Pond, that facility ceased to exist.

A portion of the remaining clay core dikes were salvaged, and additional soil embankments were constructed to outline the footprint of both Upstream Raise 91 and the adjacent Upstream Raise 92. A new composite liner was completed over the regraded Upstream Raise 91 floor and embankments in 1992, the specifics of which are discussed in more detail in Section 6.0. In addition, composite liner was installed in the area between Upstream Raise 91 and Upstream Raise 92 in 2016. This additional liner completes a continuous composite-lined area between Upstream Raise 91 and Upstream Raise 92. Typical west-east and south-north cross sections through Upstream Raise 91 are shown on Figure 3 along with details of the existing composite liners.

2.3 Upstream Raise 91 and Upstream Raise 92

Upstream Raise 91 and Upstream Raise 92 have been designed, constructed, and operated as separate units. As such, the groundwater associated with these facilities are monitored as separate units under the CCR Rule and NDDEQ regulations. The key factors that differentiate these units are described below.

- **Design and Construction Components:** The composite liner systems for Upstream Raise 91 and Upstream Raise 92 were constructed at different times with different components. Each impoundment relies on separate sumps and drainage systems. The separate liner systems, drainage systems, and sumps allow for the water within these impoundments to be managed through different closure timeframes.
- **Operations:**
  - Upstream Raise 92 is anticipated to cease receipt of sluiced FGD material at the end of 2020.
  - Upstream Raise 91 began operating in its current condition in 2015. Beginning in 2021, Upstream Raise 91 will be the only facility for FGD material deposition at CCS and the primary facility for fly ash and bottom ash deposition. Fly ash and bottom ash must be deposited concurrently with FGD due to the upstream raise design.
- **Groundwater Flow Regime:**
  - The groundwater flow direction beneath Upstream Raise 91 is generally from south to north toward Lower Samuelson Slough, with a slight west to east flow component. The gradient beneath the facility appears to be relatively consistent.
  - The groundwater flow direction beneath Upstream Raise 92 is generally from west to east, with a slight south to north component. The gradient is generally consistent with Upstream Raise 91 on the west side of the facility. On the east side of the facility, the gradient decreases due to an apparent break in the groundwater flow regime where groundwater appears to flow generally toward Sayler Slough as opposed to Lower Samuelson Slough.

2.4 Upstream Raise 91 Operation and Lifespan

The structural perimeter of Upstream Raise 91 is constructed using bottom ash and fly ash, while FGD material is contained in the center of the facility. While the primary use of Upstream Raise 91 is the disposal of FGD material, the design of this facility requires the deposition of bottom ash and fly ash for its construction. As a result, fly ash, bottom ash, and FGD material are functionally inseparable waste streams that must be deposited together for the continued safe operation of Upstream Raise 91 (see Figure 4). The perimeter foundation drainage layer of Upstream Raise 91 is constructed using the relatively permeable bottom ash and also include perforated drainage piping. As construction proceeds vertically upward with continued FGD material deposition, a perimeter bottom

ash drainage layer and a structurally competent fly ash shell are constructed on the exterior of the facility. The bottom ash drainage layer increases the factor of safety against potential slope movement by keeping the phreatic surface toward the center of the facility, while the exterior fly ash slopes provide a stable trafficking surface for haul trucks and limits erosion due to precipitation. Inherent physical properties of both the bottom ash and fly ash materials are well-suited to serve as materials to construct the upstream raise in compliance with the engineering design. Construction progresses in an upstream direction (toward the middle of the facility) to keep CCR over the lined footprint and at engineered slopes designed to increase stability and capacity and minimize the effects due to erosion.

Process water used to convey FGD material to the interior of Upstream Raise 91 passively drains through bottom ash perimeter containment berms and/or supplemental surficial piping to the foundation drainage system. From the drainage system within the foundation, the process water eventually flows to the northwest corner of Upstream Raise 91 where it is directed to the Drains Pond System.

Starting in December of 2020, Upstream Raise 91 will be the only facility for FGD deposition at CCS and the primary facility for fly ash and bottom ash deposition. There is an estimated 6,000,000 cy of capacity for waste disposal remaining in Upstream Raise 91, with an expected lifespan of approximately 10 years (depending on the rate of FGD deposition).

Upstream Raise 91 was designed and constructed to have a bottom ash drainage layer on the north, south, and west sides of the facility. As the facility construction progresses vertically, the perimeter foundation bottom ash drainage layer and fly ash shell will be raised on these three sides as described above. The east side is designed to buttress against the existing fly ash shell and perimeter foundation bottom ash drainage layer of Upstream Raise 92, and no drainage or structural zone is required for stability (Figure 3). Since the east side of Upstream Raise 91 buttresses onto the west slope of Upstream Raise 92, GRE plans to pursue construction of a new composite liner (likely Geosynthetic Clay Liner and 60-mil geomembrane) up the west slope of Upstream Raise 92 that is tied into the Upstream Raise 91 composite liner. This portion of the liner will be constructed to be consistent with the CCR Rule's definition of a liner and therefore is not a subject of this request to submit an alternative liner application.

3.0 CCR RULE COMPLIANCE

As part of the application requesting approval to submit an alternative liner demonstration, the EPA has requested documentation showing full compliance with applicable requirements in 40 CFR part 257 subpart D except for 40 CFR 257.71(a)(1). Upstream Raise 91 has maintained compliance with all CCR requirements to date. Additional documents pertaining to CCR requirements that are not included as part of this demonstration are available on GRE's publicly accessible CCR website, located at: https://ccr.greatriverenergy.com/.

3.1 Owner's Certification of Compliance – 257.71(d)(1)(i)(A)

As part of the application package, 40 CFR 257.71(d)(1)(i)(A) requires "A certification signed by the owner or operator that the CCR unit is in full compliance with this subpart except for 40 CFR 257.71(a)(1)." A certification letter signed by GRE for Upstream Raise 91 stating full compliance with applicable requirements in 40 CFR part 257 subpart D, except 40 CFR 257.71(a)(1), is attached as Appendix A1.

3.2 Location Restrictions – 257.71(d)(1)(i)(B)(*3*)

In addition to the certification, 40 CFR 257.71(d)(1)(i)(B)(*3*) requires "Documentation that the unit meets all the location restrictions under 40 CFR 257.60 through 257.64" be included as part of the application letter. Location

Restrictions Demonstrations were finalized for Upstream Raise 91 in October 2018 and are included as Appendix A-2 (Golder 2018). Upstream Raise 91 meets the requirements detailed in 40 CFR 257.60 through 257.64, summarized as follows:

- 40 CFR 257.60 – Placement above the uppermost aquifer
  - Based on groundwater elevations, the base of the liner system for Upstream Raise 91 is above the upper limits of the uppermost water bearing zone and no intermittent, recurring or sustained hydraulic connection between any portions of the base of the CCR units and the uppermost aquifer exists.
- 40 CFR 257.61 – Wetlands
  - Upstream Raise 91 was constructed as an above-grade impoundment with grass covered perimeter earthen embankments and is located several hundred feet uphill of Samuelson Slough (closest surface water body). There are no visual indications suggesting the impoundment is located in wetlands. In addition, the NDDEQ, as part of the permit requirements of each facility, has previously accepted that Upstream Raise 91 is not located in wetlands.
- 40 CFR 257.62 – Fault areas
  - As evidence of being outside of fault areas, United States Geological Survey's (USGS) Earthquake Hazards Program's U.S. Quaternary Faults and Folds Database information was reviewed, including a map of the known faults in the contiguous United States. No known quaternary faults are located in the state of North Dakota (USGS 2020). Upstream Raise 91 is not located within 200 feet of a fault (or the outermost damage zone of fault) that has had displacement in Holocene time.
- 40 CFR 257.63 – Seismic impact zones
  - A seismic impact zone is defined as an area having a 2% or greater probability that the maximum expected horizontal acceleration, expressed as a percentage of the earth's gravitational pull (g), will exceed 0.10 g in 50 years. Based on a review of USGS information, the majority of North Dakota, including CCS, is given a 2% probability of exceeding 0.02 g in 50 years, below the 0.10 g threshold for defining a seismic impact zone (Petersen, et al. 2019).
- 40 CFR 257.64 – Unstable areas
  - The Upstream Raise 91 facility was assessed for the presence of unstable areas based on a review of historic soil, geologic, and geomorphologic references. Upstream Raise 91 is generally constructed over a glacial till layer consisting of sand and silty-clay soils. Glacial till varies in thickness from 20 feet to several hundred feet in the area of CCS. No prior mining has occurred within the footprint of the facility, or adjacent to the facility, that would undermine the stability of the facility. No significant fills, excavations, or structures are present adjacent to the facilities. Based on this assessment, Upstream Raise 91 is not located in an unstable area.

3.3 Structural Stability and Safety Factor Assessment – 257.71(d)(1)(i)(B)(*4*) and 257.71(d)(1)(i)(B)(*5*)

As part of the application package, 40 CFR 257.71(d)(1)(i)(B)(4) requires "The most recent structural stability assessment required at 40 CFR 257.73(d)" and 40 CFR 257.71(d)(1)(i)(B)(5) requires "The most recent safety factor assessment required at 40 CFR 257.73(e)." The most recent version of the structural stability assessments

and safety factor assessments for Upstream Raise 91 has been included in Appendix A-3 (Golder 2016). These documents demonstrate that Upstream Raise 91 meets the applicable structural stability and safety factors.

4.0 GROUNDWATER MONITORING NETWORK – 257.71(D)(1)(I)(B)(*1*)

For documenting the compliance certification, 40 CFR 257.71(d)(1)(i)(B)(*1*) requires:

> "Documentation that the groundwater monitoring network meets all the requirements of 40 CFR 257.91. This must include documentation that the existing network of groundwater monitoring wells is sufficient to ensure detection of any groundwater contamination resulting from the impoundment, based on direction of flow, well location, screening depth and other relevant factors. At a minimum, the documentation must include all of the following:
>
> i) Map(s) of groundwater monitoring well locations in relation to the CCR unit(s) that depict the elevation of the potentiometric surface and the direction(s) of groundwater flow across the site;
>
> ii) Well construction diagrams and drilling logs for all groundwater monitoring wells;
>
> iii) Maps that characterize the direction of groundwater flow accounting for temporal variations; and
>
> iv) Any other data and analyses the owner or operator of the CCR surface impoundment relied upon when determining the design and location of the groundwater monitoring network."

As part of the CCR Rule, a monitoring well network meeting the requirements of 40 CFR 257.91 has been used to monitor the groundwater upgradient and downgradient of Upstream Raise 91. The current CCR groundwater monitoring system certification for CCS is included as Appendix B1 (Golder 2019a). A summary of CCR Rule requirements associated with the groundwater monitoring network and where they are addressed in this document can be found in Table 2.

Table 2: Monitoring Well Network Documentation

CCR Rule Citation 40 CFR Part 257	Information Requested	Where Addressed in this Demonstration
71(d)(1)(i)(B)(1)(i)	Map(s) of groundwater monitoring well locations in relation to the CCR unit(s) that depict the elevation of the potentiometric surface and the direction(s) of groundwater flow across the site;	Section 4.1.3 and Figures 5, 6, and 7
71(d)(1)(i)(B)(1)(ii)	Well construction diagrams and drilling logs for all groundwater monitoring wells;	Section 4.4.1 and Appendix B-7
71(d)(1)(i)(B)(1)(iii)	Maps that characterize the direction of groundwater flow accounting for temporal variations;	Section 4.1.3 and Figures 5, 6, and 7
71(d)(1)(i)(B)(1)(iv)	Any other data and analyses the owner or operator of the CCR surface impoundment relied upon when determining the design and location of the groundwater monitoring network.	Section 4.3 and Appendix B-3, Appendix B-4, Appendix B-5, and Appendix B-6

4.1 Description of Site Hydrogeology

The area surrounding CCS is primarily characterized by the presence of mixed glacial deposits. The following section describes the regional and site geology and hydrogeology.

4.1.1 Regional and Site Geology

CCS and McLean County are situated at the eastern-most extent of the Williston Basin, a structural and sedimentary basin (USGS 1999). The region is characterized by the presence of glacial drift, reaching thicknesses of several hundred feet, and overlying the Sentinel Butte Member, the source of commercially mined coal in the direct vicinity of CCS (Falkirk 1979). The Sentinel Butte Member is the highest strata of the Paleocene Fort Union Formation, overlying the Tongue River, Ludlow, and Cannonball Members (USGS 1999). The Sentinel Butte Member is marked by drab-gray units, separating it from the lower Tongue River Member.

The near-surface site geology of CCS includes unconsolidated surficial deposits of the Coleharbor formation consisting of stratified and unstratified glacial drift. Geologic conditions are heterogeneous, with materials varying from silty clay and sandy clay till to interbedded sand lenses and discontinuous coal seams (Appendix B-4, CPA/UPA 1989).

4.1.2 Stratigraphic Cross Sections

Stratigraphic cross sections were compiled based on boring information from current CCR monitoring wells and historical monitoring wells and boreholes (Appendix B-2). Borings within lined facility boundaries were completed prior to composite liner construction.

As shown in the cross sections, within the area of the site there is variability in the near-surface geologic units encountered. Discontinuous seams of coal are located throughout the site, in addition to gravel, sand, silt, and clay.

Note that boring information has been projected to applicable sections and that historical borings may be truncated at the top of liner or current existing ground surface grades due to changes in site geometry since borings were completed.

4.1.3 Site Hydrogeology

Regional groundwater flow of the uppermost water-bearing unit in the vicinity of CCS is a subtle expression of the surface topography, which is influenced by the configuration of the eroded bedrock.

- Map(s) of groundwater monitoring well locations in relation to the CCR unit are included as Figures 5 and 6. In addition to well and facility locations, a potentiometric surface of the shallow groundwater has been developed from the October 2019 and April-May 2020 detection monitoring events and included on the maps to show direction of groundwater flow accounting for temporal variation.
- A map showing a potentiometric surface of the shallow groundwater across the entire CCS site was developed from the April-May 2020 monitoring well and piezometer information and is included as Figure 7.

Based on the groundwater elevations (shown in Figures 5, 6, and 7), the shallow groundwater at the CCR facilities generally follows surface topography, flowing to the east and north towards Lower Samuelson Slough and Sayler Slough. Paired wells (shallow and deep) located north and northeast of Upstream Raise 91 indicate that an upward gradient is common across the site. Therefore, the horizonal gradient beneath Upstream Raise 91

is likely to be the primary component to groundwater flow and impact from a conceptual release would likely remain in the uppermost portion of the shallow water-bearing unit (Appendix B-3, Braun 1990).

The groundwater gradient across Upstream Raise 91 was estimated from the April 2020 groundwater levels, and ranges from 0.01 to 0.02 feet per feet (ft/ft). Slug testing was performed at several site monitoring wells in 2007 and resulting estimated hydraulic conductivity values ranged between 8 x 10^{-3} cm/sec (22.6 feet/day) and 1 x 10^{-4} cm/sec (0.28 feet/day). These slug test results are representative of the sandier units screened in these well, but geologic conditions at Upstream Raise 91 are significantly more heterogeneous and this field testing is not representative of widespread conditions beneath the facility. Approximately 10 to more than 50 feet of low-permeability soil exists below the composite liner system of Upstream Raise 91 (see Appendix B-2).

Permeability tests have been conducted on nine relatively undisturbed (i.e., Shelby tube) samples obtained from relevant depths in boreholes drilled in and around the areas occupied by Upstream Raise 91 to characterize the hydraulic conductivity of the near-surface native soils. The locations of the boreholes from which the samples were obtained are shown in Figure 8. The results of the permeability tests are summarized in Table 3 and indicate that native soils underlying Upstream Raise 91 are characterized by hydraulic conductivity values ranging from 4.6x10^{-8} cm/sec to 1.8x10^{-6} cm/sec.

Table 3: Permeability Test Results for Native Soils

Year	Borehole	Sample Depth	Soil Description	Hydraulic Conductivity
2014	DP-A	25 feet	Clayey silt, brown	8.6x10^{-8} cm/sec
2014	DP-B	15 feet	Silty clay, trace gravel, dark brown	4.6x10^{-8} cm/sec
2014	DP-C	25 feet	Clayey sand, dark brown, moist	1.2x10^{-7} cm/sec
2014	DP-D	20 feet	Sandy silty clay, dark brown, moist	1.8x10^{-6} cm/sec
2002	SW16-8	76 feet	Clay, some silt, little sand, yellowish-brown	3.9x10^{-7} cm/sec
2001	BH-8	61 feet	Clay, some sand and gravel, dark grayish-brown	8.3x10^{-8} cm/sec
1978	SAP-1	3.5 feet	Silty clay	4.2x10^{-7} cm/sec
1978	SAP-8	12.5 feet	Lean clay	1.5x10^{-7} cm/sec
1978	SAP-10	3.5 feet	Lean clay	1.8x10^{-7} cm/sec
Geometric mean				1.9x10^{-7} cm/sec

4.2 Release Conceptual Model

A hypothetical subsurface release from Upstream Raise 91 would be expected to migrate vertically downward through the unsaturated zone to the uppermost groundwater, approximately 5 to 15 feet below the bottom of the composite liner system, before flowing toward downgradient monitoring wells (see Figure 9). As described in

Section 4.1.3, the horizontal hydraulic gradient beneath Upstream Raise 91 is likely the primary component to groundwater flow and an upward hydraulic gradient also generally exists on site, indicating a conceptual release would likely stay in the shallow groundwater system and not migrate vertically. The downgradient wells discussed below are positioned along the downgradient edges of the CCR facility to detect a release, if occurring.

4.3 Information Reviewed

Golder reviewed information from the operating record documenting the design, installation, and development of the monitoring wells and/or describing hydrogeologic conditions at the site to assess the design and location of the groundwater monitoring network. The information reviewed included:

- Braun Environmental Laboratories. 1990. Hydrogeological Analysis Annual Report, Coal Creek Station, McLean County, North Dakota. December 1990. (included as Appendix B-3)
- Cooperative Power and United Power Associations (CPA/UPA). 1989. Application to Renew Permit SU-033 – Coal Creek Station, McLean County, North Dakota. Submitted to the North Dakota State Department of Health. February 1989. (Appendix B-4)
- Environmental and Regulatory Services Division – Cooperative Power Association (ERSD/CPA). 1993. Coal Creek Station 1993 Water Quality Monitoring Report. Submitted to the North Dakota State Department of Health and Consolidated Laboratories. 1993. (included as Appendix B-5)
- Dames & Moore. 1991. Revised Water Quality Monitoring Plan, Coal Creek Station for Cooperative Power Association. December 1991. (included as Appendix B-6)
- Falkirk Mining Company. 1979. Land Use Analysis/Technical Examination/Environmental Assessment Record – Falkirk Coal Lease Application M-31053 (ND). Submitted to the United States Department of the Interior, July 1979. https://books.google.com/books?id=KwUyAQAAMAAJ&lpg=PP1&ots=vAdnubfhR2&dq=land%20use%20analysis%20falkirk%20M31053&pg=PT2#v=onepage&q&f=false
- United States Geological Survey. 1999. Fort Union Coal in the Williston Basin, North Dakota: A Synthesis. Chapter WS in 1999 Resource Assessment of Selected Tertiary Coal Beds and Zones in the Northern Rocky Mountains and Great Plains Region, U.S. Geological Survey Professional Paper 1625-A. https://pubs.usgs.gov/pp/p1625a/Chapters/WS.pdf

As described in subsequent sections, the information in these reports supports our conclusion that the monitoring well network meets the applicable requirements.

4.4 Monitoring Wells

The monitoring well network for Upstream Raise 91 consists of three downgradient wells (MW-49, MW-91-1 and MW-51), positioned along the northern boundary of the facility (see Figures 5 and 6). There are four monitoring wells (MW-DP3, MW-91-2, MW-75, and MW-16-6) that are upgradient of Upstream Raise 91 used to evaluate upgradient water quality (Figures 5 and 6).

4.4.1 Monitoring Well Geologic Conditions

Monitoring well construction diagrams and drilling logs for the Upstream Raise 91 monitoring wells are included in Appendix B-7. Table 4 and Appendix B-7 present the variability of the screened geologic units for wells associated with Upstream Raise 91 and demonstrate that heterogeneity is an important consideration for the groundwater

monitoring system and statistical methods. The monitoring wells associated with Upstream Raise 91 are screened in the upper most water bearing zone. There is variation in the material each well is screened in due to the non-uniformity of the unconfined layers of the glacial till.

Table 4: Upstream Raise 91 Monitoring Well Screened Lithologies

Location	Well ID	Geologic Unit(s) Screened In
Upgradient	MW-DP3	Fill, Coal, Fat Clay
	MW-91-2	Fat Clay, Coal
	MW-75	Clayey Silt, Silty Sand
	MW-16-6	Sandy Lean Clay, Coal, Lean Clay
Downgradient	MW-49	Sandy Gravelly Clay, Sandy Silt, Fat Clay (Shale)
	MW-51	Silty and Gravelly Sand, Lean Clay
	MW-91-1	Sand with Silt and Gravel, Fat Clay

4.4.2 Vertical Placement of Monitoring Well Screens

The upgradient and downgradient monitoring wells associated with Upstream Raise 91 are installed and screened at appropriate depths to monitor groundwater in the uppermost water bearing zone. As described in Section 4.2, a release from Upstream Raise 91 is expected to move laterally in the uppermost water bearing zone beneath the facility toward the monitoring wells. Therefore, these wells are expected to detect a release from the facility.

A pair of wells (MW-9 and MW-10) located east of MW-51 along the downgradient boundary of Upstream Raise 92 support the placement of the well screens in the Upstream Raise 91 monitoring network. MW-10 is screened relatively shallow (15-25 feet below ground surface) to intercept the uppermost water bearing zone, and MW-9, located approximately 7 feet from MW-10, is screened deeper (43-53 feet below ground surface). While these wells are not part of the monitoring network for Upstream Raise 91, they provide important information on the groundwater system in the vicinity. Two observations have been made from this well pair that support the placement of Upstream Raise 91 monitoring well screens.

- An upward gradient exists between MW-9 and MW-10 which is to be expected for a groundwater discharge area. Groundwater in this area discharges to the nearby Samuelson Slough (Appendix B-3, Braun 1990). With an upward gradient, potential impacts to groundwater would be expected to be observed in wells screened in the uppermost water bearing zone.
- Differences in chloride, sulfate, and total boron concentrations in samples collected from MW-9 and MW-10 are shown on Figures 10, 11 and 12. MW-10 (shallower well) was impacted by the subsurface release from the legacy unit (South Ash Pond), while chloride, sulfate, and total boron concentrations in MW-9 were stable and apparently unaffected by the subsurface release from the legacy unit. This observation indicates that the Upstream Raise 91 downgradient monitoring wells are screened to intercept groundwater in the uppermost water bearing zone and are expected to detect a release.

4.4.3 Downgradient Monitoring Well Spatial Conditions

Based on site geometry and the groundwater flow direction, the spacing of the downgradient wells along the northern boundary of Upstream Raise 91 are adequate to accurately represent the quality of groundwater passing the waste boundary, ensure the detection of groundwater contamination in the upper most aquifer, and monitor all potential contaminate pathways. The number and spacing of the downgradient monitoring wells were selected based on the hydrogeologic conditions at the site, the areal extent of Upstream Raise 91 along the downgradient boundary, and the monitoring network previously approved by the NDDEQ (North Dakota State Director) so that impacts to groundwater quality in the uppermost water bearing unit can be detected if a subsurface release were to occur.

Groundwater has been monitored at CCS since the late 1970s. The initial groundwater monitoring system downgradient of Upstream Raise 91 was installed in 1988 and included three wells (MW-49, MW-50, and MW-51). Annual groundwater monitoring reports that include these wells have been submitted to the NDDEQ since 1989. The initial groundwater monitoring system was evaluated by Dames & Moore in 1991 (Appendix B-6, Dames & Moore 1991) and a conclusion from this report indicated the “current ground water and surface water locations are adequate to effectively monitor known water quality conditions.”

In 1992, the monitoring locations in the program were re-evaluated by GRE environmental personnel and approved by the NDDEQ, so that the “program could track representative and significant data” (Appendix B-5, ERSD/CPA 1993). Upstream Raise 91 had recently been constructed and composite lined at this time, as part of corrective actions at the site associated with the legacy unit, which was part of the reason the groundwater monitoring program was re-evaluated. The location of the three downgradient wells were deemed adequate by GRE environmental personnel and the NDDEQ for monitoring the newly composite-lined Upstream Raise 91. Groundwater beneath Upstream Raise 91 continued to be monitored via the North Dakota state program, with results being submitted to the NDDEQ annually.

Golder re-evaluated the monitoring network as a part of the CCR Rule network certification. This evaluation took into consideration the historical monitoring well network approved by the NDDEQ. The water levels decreased in one of the existing downgradient monitoring wells (MW-50, last sample collected in 2014) to the point that insufficient water was able to be measured and collected for sampling. Therefore, a new monitoring well (MW-91-1) was installed near MW-50, screened in the uppermost water bearing zone, and was included as part of the downgradient monitoring well network. Golder’s review, which is summarized in the groundwater monitoring system certification (Appendix B-1, Golder 2019a), indicated that the three monitoring wells along the downgradient side of Upstream Raise 91 (MW-49, MW-91-1, and MW-51) were adequate to meet the requirements of 40 CFR 257.91(b).

The three downgradient monitoring wells along the northern boundary of Upstream Raise 91 were located based on observations that show groundwater flows from southwest to northeast below the facility towards Lower Samuelson Slough (see Section 4.1.3). Upstream Raise 91 lies adjacent to and in between Upstream Raise 92 and the Drains Pond System, which are also monitored as a part of the CCR Rule program. Since these facilities are monitored separately as described in Section 2.2, the effective downgradient length along the north boundary of Upstream Raise 91 that can be monitored is approximately 1,400 feet. The three downgradient wells are positioned at an approximately even spacing downgradient of Upstream Raise 91, meaning that the wells have an average lateral spacing of approximately 465 feet.

The north embankment of Upstream Raise 91 functions as an anchor to the composite liner systems for the facility, as a utility corridor for CCR and process water conveyance piping and electrical duct banks, and as an access/haul route for equipment operating and performing maintenance onsite. The downstream slopes of the north embankment are 3 horizontal units to 1 vertical unit (3H:1V) slopes that are vegetated and are approximately 25 feet high. The slopes are too steep for drilling equipment and installation of monitoring wells. Due to the presence of utilities and heavy equipment operation on the embankment crest, the location of the CCR sluice piping, and the slope of the embankment, the downgradient monitoring wells around Upstream Raise 91 were installed at the downstream toe of the soil embankment, which is approximately 100 feet downgradient of the composite liner anchor trench along the embankment crest.

4.4.4 Upgradient Monitoring Wells

As part of the network certification evaluation, additional upgradient monitoring wells were installed in accordance with the requirements of the CCR Rule and to provide a representative range in variability of groundwater conditions upgradient of the CCR units at CCS. A review of recent groundwater levels indicates that there are four applicable upgradient wells to Upstream Raise 91 (MW-DP3, MW-91-2, MW-75, MW-16-6). These wells yield groundwater samples from the uppermost water bearing zone that represent the quality of background that has not been affected by leakage from Upstream Raise 91 as required by 40 CFR 257.91(a).

These four upgradient wells are screened in the uppermost water bearing zone. As shown in the cross sections (Appendix B-2) and the monitoring well logs (Appendix B-7), variability within the area of the site results in a range of materials within the near-surface geologic units. Discontinuous seams of coal are located throughout the site, in addition to gravel, sand, silt, and clay. This geologic spatial variability influences the water quality variability observed in the upgradient wells (see Section 5.2.1.1). The comparative statistical approach selected for detection monitoring (intra-well analysis) does not rely on the upgradient wells capturing all the possible upgradient waters.

In addition to the four upgradient monitoring wells, there are several monitoring wells in the plant area being used for other programs that can also be used to evaluate further upgradient sources that may not be captured by the four designated upgradient monitoring wells. These additional upgradient wells near the plant, including a brief discussion of how upgradient sources may be impacting the wells near the plant, are discussed more in Section 5.4.1.

5.0 GROUNDWATER MONITORING PROGRAM – 257.71(D)(1)(I)(B)(*2*)

As part of the compliance documentation, 40 CFR 257.71(d)(1)(i)(B)(*2*) requires:

> “Documentation that the CCR surface impoundment remains in detection monitoring pursuant to 40 CFR 257.94 as a precondition for submitting an application. This includes documentation that the groundwater monitoring program meets the requirements of 40 CFR 257.93 and 257.94. Such documentation includes data of constituent concentrations, summarized in table format, at each groundwater monitoring well monitored during each sampling event, and documentation of the most recent statistical tests conducted, analyses of the tests, and the rationale for the methods used in these comparisons. As part of this rationale, the owner or operator of the CCR surface impoundment must provide all data and analyses relied upon to comply with each of the requirements of this part.”

At present, the groundwater monitoring system for Upstream Raise 91 remains in detection monitoring, as defined by 40 CFR 257.94. As such, groundwater at the facilities is monitored on a semi-annual basis for the parameters

listed in Appendix III of the CCR Rule. Assessment monitoring as defined in 40 CFR 257.95 has not been initiated. Groundwater Protection Standards (GWPS) have not been formally developed as described in 40 CFR 257.95(d)(2) and 40 CFR 257.95(h) due to the program remaining in detection monitoring.

The following additional information for the current groundwater monitoring program for Upstream Raise 91 has been provided to aid in the EPA's review of the site's compliance with the requirements of 40 CFR 257.93 and 257.94.

5.1 Groundwater Monitoring Data

Tables summarizing Appendix III and Appendix IV constituent concentrations for samples collected for baseline and detection monitoring from the Upstream Raise 91 monitoring wells is included in Appendix C-1.

5.2 Detection Monitoring Statistical Approach

The current CCR statistical methods certification for CCS was last revised March of 2019 and is included as Appendix C-2 (Golder 2019b). The statistical approach used at the site is based on guidance provided in the USEPA's Unified Guidance (USEPA 2009), as well as information detailed in 40 CFR 257.93 and 257.94. Further information regarding the basis for the statistical approach as well as the application of the statistical approach for detection monitoring is provided in the following sections.

5.2.1 Intra-well Statistics

Intra-well statistics (comparing compliance data to baseline data within a single well) was identified as an appropriate method for groundwater detection monitoring for Upstream Raise 91. As discussed by the EPA in the preamble to the Part A final rule (USEPA 2020a), "The regulations of 257.93(f) and (g) establish the allowable statistical approaches and the performance standards that must be met. There are some circumstances in which intra-well comparison can meet these requirements. Additional information about these approaches may be found in the Unified Guidance, which EPA relied upon, as well as 40 CFR 258."

The Unified Guidance provides procedures for both inter-well and intra-well methods: "Groundwater detection monitoring involves either a comparison between different monitoring stations (i.e., downgradient compliance wells vs. upgradient wells) or a contrast between past and present data within a given station (i.e., intra-well comparisons)" (USEPA 2009). The Unified Guidance further identifies circumstances in which intra-well comparison may be preferred over inter-well comparison. Two situations where intra-well statistics may be preferable to inter-well statistics are where spatial variability is present, and where legacy impacts not stemming from current facilities or handling practices are known to have occurred. Upstream Raise 91 has both spatial variability and historical impacts from a legacy unit.

5.2.1.1 Spatial Variability

The Unified Guidance indicates that where spatial variability is evident, "the statistical approach would need to be modified so that distinct wells are treated as individual populations with statistical testing being conducted separately at each one (i.e., intrawell comparisons)" (USEPA 2009). Per the Unified Guidance, "Confounding results stemming from spatial variability can be eliminated" through the use of intra-well statistics (USEPA 2009). Specifically, the Unified Guidance notes that "substantial differences in mean concentration levels can *invalidate* interwell, upgradient-to-downgradient comparisons and point instead toward *intrawell* tests" (USEPA 2009, original emphasis included).

Due to the heterogeneity of the glacial geology at CCS, spatial variability is displayed throughout the groundwater monitoring networks. Use of intra-well statistics allows comparisons to be made on a per well basis, which avoids comparisons being made between differing geologic/geochemical conditions. The Unified Guidance identifies spatial variability as “statistically identifiable differences in mean and/or variance levels (but usually means) across the well field (i.e., spatial non-stationarity) (USEPA 2009).”

Three lines of evidence demonstrate the geochemical spatial variability across the site. First, side-by-side box plots of the Appendix III parameters for the upgradient wells are provided in Figures 13 through 19. The Unified Guidance notes that side-by-side box plots “can be further employed to screen for possible spatial variation in mean levels (USEPA 2009),” Further, “the extent to which apparent differences in mean levels seem to be real rather than chance fluctuations can be examined” through the comparison of side-by-side box plots (USEPA 2009). The side-by-side box plots for the four upgradient wells display variable water quality in the area upgradient of Upstream Raise 91.

Analysis of variance (ANOVA) testing provides further confirmation of upgradient spatial variability, as described in the Unified Guidance (USEPA 2009). Determination of the distribution for ANOVA testing is based on the residuals, or the calculated difference between the observed values and the values predicted by the ANOVA model. ANOVA testing was conducted for data collected from the upgradient locations between the start of the baseline period and the second quarter (Q2) 2020 detection monitoring event. For each of the seven Appendix III parameters, either variation (in the case of parametric ANOVA tests for parameters with residuals exhibiting normal or transform-normal distributions), or difference (for non-parametric ANOVA tests for parameters with residuals exhibiting non-normal distributions) is indicated at the 5% significance level (α = 95%). The Appendix III parameters exhibit ANOVA significance between upgradient wells, indicating statistically significant geochemical spatial variability. As noted by the Unified Guidance, “substantial differences among the mean levels at a set of uncontaminated sampling locations [such as the tested upgradient wells] are suggestive of natural spatial variability (USEPA 2009,).” ANOVA evaluation of the four upgradient wells identified significant difference between well means or medians. The Unified Guidance indicates that pooling should not occur among well means or medians determined to be significantly different using ANOVA (USEPA 2009) and therefore inter-well statistical analyses are not recommended in this situation. Appendix C-3 provides results of ANOVA testing on data collected at wells upgradient from Upstream Raise 91

A major ions trilinear diagram (piper diagram), developed from water chemistry results collected from the upgradient wells in the CCR groundwater program for each of the four CCR monitoring units (Upstream Raise 91, Upstream Raise 92, Southeast 16, and the Drains Pond System), show the variability in water types across the site in upgradient wells (Figure 20). Data used for constructing the piper diagram were collected during four monitoring events between 2017 and 2020.

As recommended by the Unified Guidance, the evidence of spatial variability amongst the upgradient wells has driven the selection of an intra-well statistical approach for Upstream Raise 91.

5.2.1.2 Historical Impacts – Hydrogeological Evaluation

In addition to the identification and evaluation of spatial variability discussed above, the Unified Guidance indicates that intra-well testing is also useful when there are historical impacts. “Another advantage using intrawell background is that a *reasonable baseline* for tests of future observations can be established at historically contaminated wells. In this case, the intrawell background can be used to track the onset of even more extensive contamination in the future” (USEPA 2009, original emphasis included).

Historical subsurface releases from legacy CCR facilities are known to have impacted groundwater levels and chemistry at CCS. Those facilities have been removed and/or closed, and new facilities with engineered composite liner systems have been constructed. However, the monitoring well network is likely continuing to detect historical impacts from the legacy unit due to the hydrogeological conditions described in Section 4.1.

To evaluate the potential for ongoing historical impacts on downgradient groundwater quality, the travel time in the unsaturated/vadose zone and uppermost water bearing zone were estimated using simplified, yet conservative, analytical methods for advective transport. The total travel time for potential subsurface impacts to affect downgradient well groundwater quality is based on:

- Vadose zone thickness, i.e., the vertical separation between the base of the composite liner system and the uppermost water bearing zone (see Appendix A-2 (Golder 2018) and Appendix B-2),
- Site-specific hydraulic conductivity values and material properties from laboratory testing of the native soil samples from the vadose zone (described in Section 4.1.3),
- Site-specific hydraulic conductivity values of the uppermost water bearing zone from slug testing conducted in upgradient and downgradient monitoring wells adjacent to Upstream Raise 91 (described in Section 4.1.3),
- Estimated effective porosity of glacial till, and
- Groundwater gradients across Upstream Raise 91 (described in Section 4.1.3).

Estimates of the above properties at the site were used to evaluate unsaturated flow from the bottom of the composite liner to the uppermost water bearing zone (vadose zone) and saturated flow through the uppermost groundwater to the downgradient monitoring wells. The total estimated travel time (through the vadose zone and uppermost groundwater) for a subsurface release from the near the north side of Upstream Raise 91 to the downgradient monitoring well MW-91-1 is approximately 13 years, while the total travel time from the southwest side of Upstream Raise 91 to MW-91-1 is approximately 33 years. These travel time estimates are conservative since they are based on advective transport in homogeneous, laterally continuous, sandy glacial till, and do not incorporate retardation in transport processes or travel time due to sorption or dispersion. In addition, site heterogeneity, e.g., in groundwater flow paths, hydraulic conductivity, soil and contaminant properties, are not accounted for in this estimate and will also influence travel time; such variations will generally increase travel times.

Based on this analysis, it is likely that groundwater samples from the downgradient monitoring wells continue to be affected by the historical impacts from the legacy unit even though the legacy unit was removed and corrective measures were implemented. This provides another basis for using intra-well comparisons as they allow for a reasonable baseline (reflective of historic impact from the legacy unit) to be established so that future monitoring can focus on identifying impacts from Upstream Raise 91.

5.2.1.3 Historical Impacts – Geochemical Evaluation

Historical impacts from legacy facilities may also be able to be evaluated using geochemical information. By comparing the water types from historical conditions to those of more recent conditions as well as the water within Upstream Raise 91, an evaluation can be performed to determine the similarities of source water. Piper diagrams (also referred to as trilinear diagrams), are a visualization tool useful to compare the chemistry of different water.

The below discussion supports the conclusion that the legacy facilities have impacted groundwater and that Upstream Raise 91 does not appear to be negatively influencing downgradient water quality.

Piper diagrams for groundwater samples with the full suite of major cations and anions collected between 1988 and the present from Upstream Raise 91 downgradient monitoring wells MW-91-1, MW-49, and MW-51 are presented in Figures 21, 22, and 23, respectively. The symbols for data associated with MW-91-1, MW-49, and MW-51 are color coded according to the dates when they were sampled. These colors were included to help the reader understand the overall temporal “trends” within the datasets. The Piper diagrams also include groundwater samples from Upstream Raise 91 upgradient monitoring wells (MW-16-6, MW-75, MW-91-2, and MW-DP3) as an indicator of unimpacted groundwater. As well as water samples taken from within the current CCR surface impoundments (UR91-Sump and UR92-Sump), water samples from the legacy unit (SW-106, SW-126, SW-127), and water samples from synthetic precipitation leached procedure (SPLP) testing of site CCRs, which are likely representative of the water quality of potential seepage from the CCR facilities at CCS.

Groundwater quality associated with samples collected from MW-49 and MW-51 have changed over their respective monitoring periods. Water quality data associated with historical samples plot closer to the water samples collected from within the CCR surface impoundments (SPLP, Sumps, and Pond Water) on the Piper diagrams, which would be indicative of seepage from the facility. This is consistent with the site history as discussed in Section 2.0, in which seepage was noted from the legacy unit (South Ash Pond) prior to removing this facility and constructing new facilities with composite liner systems. More recent water quality data associated with samples collected since the initiation of the CCR program plot further from water samples collected from within the CCR surface impoundments on the Piper diagrams. The data associated with these samples are within the range of water quality data associated with unimpacted upgradient monitoring wells, indicating that the removal of the South Ash Pond and construction of Upstream Raise 91 has improved groundwater conditions beneath and surrounding Upstream Raise 91.

Water quality data associated with samples from MW-91-1 have been relatively unchanged over the testing period and plot on the Piper diagrams within the range of unimpacted upgradient monitoring wells. This indicates that impacts from seepage out of the South Ash Pond are not apparent since MW-91-1 was first sampled in 2018.

Without baseline groundwater quality data collected prior to impacts from the South Ash Pond at MW-49 and MW-51, it is not possible to determine if groundwater downgradient of Upstream Raise 91 has returned to pre-impact conditions. If new impacts were occurring from Upstream Raise 91, a shift towards the water quality observed within the CCR surface impoundments would be expected. However, observations from water quality data for MW-49 and MW-51 are indicating a shift away from water quality observed within the CCR surface impoundments, suggesting no new impacts are occurring from Upstream Raise 91.

5.2.2 Baseline Statistics

As part of the detection monitoring program for Upstream Raise 91, comparative statistical analysis is performed following each monitoring event to determine whether concentrations of the Appendix III parameters are potentially statistically significant in comparison to baseline limits. Original baseline limits were developed using samples collected at each well as part of the baseline monitoring conducted prior to the start of detection monitoring. The baseline data for all constituents, as determined by the monitoring programs, is periodically reviewed to determine if recent results that are not statistically significant in comparison to baseline values can be incorporated into an updated baseline period. This review for baseline data occurs approximately every two to three years, based on the semi-annual sampling frequency during detection monitoring as recommended in the

USEPA's Unified Guidance (USEPA 2009), or roughly following collection of every four to eight comparative samples. A baseline update was conducted for the wells monitoring Upstream Raise 91 following the Q2 2019 detection monitoring event, following collection of four comparative samples as part of the detection monitoring program.

Statistical limits for the detection monitoring programs at Upstream Raise 91 have been made with either a parametric or non-parametric method for each constituent-well pair. The statistical method varies between constituents and has been selected based on the percentage of non-detect values in the baseline period and the baseline data distribution for each constituent at each well, in accordance with recommendations within the Unified Guidance (USEPA 2009).

5.2.3 Parametric Detection Monitoring Method – Shewhart-CUSUM Control Charts

For those constituent-well pairs where concentrations of a given analyte are normally or transform-normally distributed and have equal to or greater than 50% detections, Shewhart-CUSUM control charts are used for comparative statistics. The Unified Guidance (USEPA 2009) notes that Shewhart-CUSUM control charts use two separate evaluation procedures. The Shewhart evaluation procedure is similar to a parametric prediction limit, comparing compliance measurements to a baseline limit. The CUSUM, or cumulative summation, evaluation procedure analyzes new measurements against prior compliance measurements. The mean and standard deviation of the baseline dataset are used to calculate the limit.

Shewhart-CUSUM control charts were chosen as the primary statistical method for the detection monitoring program for a number of reasons. First, control charts are identified by the Unified Guidance as a "core strategy for detection monitoring" (USEPA 2009). As such, control charts have been identified as an appropriate statistical method for use in detection monitoring programs and are further identified as one of the explicitly stated options for statistical methods to use for CCR programs under 40 CFR 257.93. Second, control charts show increased sensitivity to gradual trends and shifts within datasets due to the dual evaluation process built into the methodology. Per the Unified Guidance (USEPA 2009), the two portions of the Shewhart-CUSUM control chart work in tandem to detect both sudden changes through the Shewhart portion of the test, and gradual increases through the CUSUM portion. For monitoring Upstream Raise 91, using a statistical methodology that is sensitive to gradual changes allows for more rapid determination of critical changes within the system.

5.2.4 Non-Parametric Detection Monitoring Method – Non-Parametric Prediction Limits

Where concentrations of a given constituent-well pair are not normally or transform-normally distributed, or contain less than or equal to 50% detections, a non-parametric prediction limit is used for comparative statistics. The non-parametric prediction limit is assigned as the highest detected value, excluding outliers, or the highest primary quantitation limit (PQL), whichever is greater.

A potential disadvantage of a control chart approach is the lack of a direct non-parametric alternative. However, per the Unified Guidance (USEPA 2009), using a paired approach of control charts for the chosen parametric methodology and non-parametric prediction limits as the non-parametric alternative addresses this perceived deficiency, providing appropriate coverage for variability in data distribution.

5.2.5 Detection Monitoring Method – Trending Data

Most statistical tests, including the two options identified for setting statistical limits within this program, assume that concentrations do not demonstrate temporal correlation. The Sen's Slope methodology is an intra-well

statistical analysis of increases or decreases in measured concentration over time measured by calculating slope of the linear relationship of concentration levels and time. Sen's Slope methodology is paired with the Mann-Kendall test to determine the statistical significance of the calculated Sen's Slope. The methodology involves examining all possible pairs of measurements in the dataset and scoring each pair to determine if a trend exists.

Where temporal trends have been identified within the proposed baseline periods, either the data is adjusted to account for trends, the time period used for the baseline period is reassessed, and/or an alternative statistical method is used to establish a limit. For datasets with statistically significant decreasing trends, no adjustments may be appropriate, and a constituent may not be considered for statistical analysis until further data is collected. In the case of decreasing trends, the Sen's Slope Methodology at a target confidence level of 99 percent serves as the alternative method for assessing compliance until the trend statistically stabilizes.

5.3 Recent Groundwater Monitoring Results

At present, the groundwater monitoring systems for Upstream Raise 91 remains in detection monitoring, as defined by 40 CFR 257.94. As such, groundwater at the site is monitored on a semi-annual basis for the parameters listed in Appendix III of the CCR Rule.

The most recent annual groundwater monitoring report is the 2019 annual report and is included as Appendix C-4 (Golder 2020a).

Comparative statistical analysis is conducted following each detection monitoring event, consisting of Appendix III parameters (40 CFR 247.93(h)(1) and (2) and 40 CFR 247.94(a) and (b), USEPA 2015). For both Shewhart-CUSUM limits and non-parametric prediction limits, the comparative statistical analysis consists of a comparison of detection monitoring results collected during the period of interest to the statistical limit calculated from the baseline data collection period.

The following definitions, specific to the statistical program but consistent with the Unified Guidance (USEPA 2009), will be used in discussion of the comparative statistical analysis:

- Elevated CUSUM – an elevated CUSUM occurs when the CUSUM is greater than the Shewhart-CUSUM limit established by the baseline statistical analysis, but the analytical result does not exceed the Shewhart-CUSUM limit. An elevated CUSUM is an indication that concentrations are gradually increasing and that analytical results may exceed the Shewhart-CUSUM limit in the future. For elevated CUSUMs in the case of two-tailed analysis, as used for field-measured pH, the CUSUM value may also be below the lower Shewhart-CUSUM limit established by the baseline statistical analysis.
- Potential Exceedance – is defined as an initial elevated CUSUM or an initial analytical result that exceeds the Shewhart-CUSUM limit or non-parametric statistical limit established by the baseline statistical analysis. Confirmatory re-sampling will determine if the potential exceedance is a false-positive or a verified statistically significant increase (SSI). Non-detect results that exceed either the Shewhart-CUSUM limit or the non-parametric statistical limit are not considered potential exceedances.
- False-positive – is defined as an analytical result that exceeds the statistical limit that can clearly be attributed to laboratory error, changes in analytical precision, or is invalidated through confirmatory re-sampling. False-positives are not used in calculation of any subsequent CUSUMs.
- Confirmatory re-sampling – is designated as the next scheduled sampling event.

- Verified SSI – is interpreted as two consecutive exceedances (the original sample and the confirmatory re-sample for analytical results, or two consecutive elevated CUSUMs) for the same constituent at the same well.

Results of the statistical analysis for the Q4 2019 and Q2 2020 detection monitoring events as the most recent detection monitoring events are shown on the tables in Appendix C5 and discussed in the following sections.

5.3.1 Potential Exceedances

Total boron at MW-51 was identified as a potential exceedance during the comparative statistical analysis for the Q4 2019 detection monitoring event. Confirmatory re-sampling for this constituent-well pair occurred during the Q2 2020 detection monitoring sampling event; results are discussed in Section 5.3.2. The statistical analysis of the results of this sampling determined the initial potential exceedance was a false positive.

Field-measured pH at MW-16-6 (upgradient) was identified as a potential exceedance during the comparative statistical analysis for the Q4 2019 detection monitoring event. Confirmatory re-sampling for this constituent-well pair occurred during the Q2 2020 detection monitoring sampling event; results are discussed in Section 5.3.2. The statistical analysis of the results of this sampling determined the initial potential exceedance was a false positive.

No potential exceedances were identified for the Q2 2020 detection monitoring event for the wells monitoring Upstream Raise 91.

5.3.2 False-Positives

No false positives were identified during the Q4 2019 detection monitoring event for the wells monitoring Upstream Raise 91.

Following the Q2 2020 confirmatory re-sampling event, the potential exceedance identified during the Q4 2019 detection monitoring event for total boron at MW-51 (downgradient) was determined to be a false-positive.

Following the Q2 2020 confirmatory re-sampling event, the potential exceedance identified during the Q4 2019 detection monitoring event for field-measured pH at MW-16-6 (upgradient) was determined to be a false-positive.

5.3.3 Trending Data

With inclusion of the Q4 2019 result and Q2 2020 result, the complete data set for calcium at MW-91-2 (upgradient, Upstream Raise 91) continues to have a statistically significant decreasing trend, based on Sen's Slope analysis at the target confidence level of 99%. Following collection of further data during the next sampling event, the calcium data for this location will be reassessed to determine if a baseline period can be established based on non-trending data.

5.3.4 Verified SSIs

Verified SSIs associated with Upstream Raise 91 have been observed as indicated below:

- Following the Q4 2019 confirmatory re-sampling event, chloride at MW-49 was identified as a verified SSI for Upstream Raise 91 based on data from the Q4 confirmatory re-sampling event. Both the potential exceedance and the verified SSI were elevated CUSUMs, with analytical results for both sampling events below the statistical limit. Chloride at MW-49 continued to be identified as a verified SSI following the Q2 2020 detection monitoring event.

- Total dissolved solids at MW-16-6 (upgradient) was identified as a verified SSI following the Q4 2019 detection monitoring event based on data from the Q4 confirmatory re-sampling event. Total dissolved solids at MW-16-6 (upgradient) continued to be identified as a verified SSI following the Q2 2020 detection monitoring event.

40 CFR 257.94(e) states the conditions under which a CCR unit must transition to assessment monitoring or complete an alternative source demonstration (ASD): "If the owner or operator of the CCR unit determines, pursuant to § 257.93(h) that there is a statistically significant increase over background levels for one or more of the constituents listed in Appendix III to this part at any monitoring well at the waste boundary specified under § 257.91(a)(2), the owner or operator must: (1) Except as provided for in paragraph (e)(2) of this section, within 90 days of detecting a statistically significant increase over background levels for any constituent, establish an assessment monitoring program meeting the requirements of § 257.95. (2) The owner or operator may demonstrate that a source other than the CCR unit caused the statistically significant levels for a constituent or that the statistically significant increase resulted from error in sampling, analysis, statistical evaluation, or natural variation in groundwater quality."

5.3.4.1 Alternative Source Demonstration – Chloride at MW-49

A successful ASD was completed within 90 days of identification of the verified SSI for chloride at MW-49 in Q4 2019 and is included in Appendix C6 (Golder 2020b). Lines of evidence indicating that the facility was not the cause of increased concentrations of chloride at MW-49 include:

- Changes in field personnel, analytical laboratories, and analytical methodologies.
- Laboratory artifacts biasing high sample concentrations.
- Geochemical signatures that are inconsistent with ash-impacted waters collected from the facility sumps.
- Elevated chloride concentrations at upgradient non-CCR facilities.

Following the Q2 2020 sampling event, chloride at MW-49 (downgradient) continued to be a verified SSI for Upstream Raise 91. An updated ASD was completed and is included in Appendix C7 (Golder 2020c) and identified similar lines of evidence in support of the ASD that were previously identified in the ASD completed for the Q4 2019 sampling event.

5.3.4.2 Upgradient Verified SSI – Total Dissolved Solids at MW-16-6

A review of site observations and measured groundwater levels as well as the geographic location of the well (Figures 5 and 6) indicate that MW-16-6, which is approximately 550 feet upgradient of the waste boundary, is hydraulically upgradient of Upstream Raise 91 (approximately 15 feet higher groundwater elevation and approximately 12 feet higher than a surface water drainage ditch between Upstream Raise 91 and the well). The groundwater contours between MW-16-6 and Upstream Raise 91 are based on measured groundwater levels in MW-16-6 and groundwater levels measured in piezometers located along the south embankment of Upstream Raise 91 (PZ-AP91C) and Upstream Raise 92 (PZ-AP92A) as shown on the stratigraphic sections (Appendix B-2). Since MW-16-6 is upgradient of Upstream Raise 91 and not at the waste boundary, the SSI was determined not to be related to Upstream Raise 91 and neither an ASD nor a transition to assessment monitoring is required.

5.4 Additional Groundwater Analysis

Additional analysis of groundwater monitoring data has been performed to support the program conclusions described above, particularly that Upstream Raise 91 remains in detection monitoring. Two sets of analyses were performed to evaluate this conclusion. The analyses performed strengthen the case that Upstream Raise 91 remains in detection monitoring and has not contributed to the degradation of downgradient groundwater quality. These analyses should be considered for discussion purposes only.

5.4.1 Inter-well Statistical Analysis

As discussed above, ANOVA evaluation of the four upgradient wells identified significant difference between well means or medians. The Unified Guidance indicates that pooling should not occur among well means or medians determined to be significantly different using ANOVA (USEPA 2009) and therefore inter-well statistical analyses are not recommended in this situation. Although not recommended by the Unified Guidance for the conditions at CCS due to spatial variability (Section 5.2.1.1) and historical impacts (Section 5.2.1.2), inter-well statistics can be performed to demonstrate that the use of intra-well statistics is not biasing the conclusion that Upstream Raise 91 remains in detection monitoring.

Inter-well statistics were conducted for Upstream Raise 91 using an inter-well prediction limit methodology. Data collected between 2015 and 2020 as part of the CCR program from four locations representing the various upgradient waters entering Upstream Raise 91 (MW-DP3, MW-91-2, MW-75, and MW-16-6) were first pooled and tested for normality using the Shapiro-Francia method, based on the number of samples within the pooled dataset. Given the documented spatial variability between the upgradient wells, as discussed in Section 5.2.1, each pooled dataset for the Appendix III parameters at the upgradient locations was determined to be non-normal and non-transform normal. As a result of the non-parametric distributions in the pooled upgradient data, each statistical limit is constrained to be the highest value observed in the upgradient wells with non-parametric prediction limits.

Detection monitoring results from the three downgradient wells are compared to these non-parametric limits in Appendix C8. For each of the three downgradient monitoring wells from Upstream Raise 91, the only Appendix III constituent that was identified above the hypothetical statistical limit in more than one consecutive sample was chloride. The majority of chloride values measured as part of the CCR monitoring program in the three downgradient wells are higher than the non-parametric limit determined from the four upgradient wells, set at the highest value within the upgradient pool. However, the downgradient chloride concentrations can be attributed to the historical impacts and/or an alternative source, as discussed below.

Figure 24 shows chloride concentrations collected at the two downgradient monitoring wells for Upstream Raise 91 that have been monitored since 1988. Chloride concentrations have generally decreased at wells MW-49 and MW-51 since being installed in 1988. Both wells pre-date the installation of the associated upgradient wells (including MW-75), the removal of the legacy unit, and the construction of Upstream Raise 91. Early concentrations at the wells are indicative of historical impacts stemming from the legacy unit (South Ash Pond), with movement towards more steady-state conditions since the legacy unit was removed and Upstream Raise 91 was constructed. The current steady-state conditions could be reflective of:

- Ongoing observations of legacy impacts in samples collected from the downgradient wells as discussed in Section 5.2.1.2.

- A return to background conditions (since no data exists for pre-impact conditions, pre-impact water quality at these locations remain unknown).
- Elevated chloride due to an alternative upgradient source other than Upstream Raise 91.

If inter-well statistics were appropriate for this site, an ASD would be pursued based on the three items discussed above. In particular, supporting information prepared as part of the successful intra-well ASD for chloride at MW-49 (Appendix C-6 [Golder 2020b] and Appendix C-7 [Golder 2020c]), would remain applicable. The intra-well ASD for chloride at MW-49 identified the Extended Basin, a cooling water recirculation pond approximately 0.75 miles upgradient of Upstream Raise 91, as a source for elevated chloride in groundwater:

- Between 1988 and 2019, chloride concentrations in the Extended Basin ranged between 158 and 300 milligrams per liter (mg/L).
- Nearby monitoring wells (MW-62, MW-63, and MW-65) located upgradient of the powerplant and immediately adjacent to the Extended Basin also have elevated chloride concentrations ranging from 8.0 to 290 mg/L indicating that water from the Extended Basin is impacting groundwater chloride concentrations.

Water from the Extended Basin also appears to be impacting wells further downgradient. The concentrations observed along the flow path between the Extended Basin and MW-49 (Figures 25 and 26) include:

- The EEG wells located east of the Extended Basin which have chloride concentrations ranging between 58 and 130 mg/L.
- Well MW-DP5, located downgradient from the plant and upgradient of the Drains Pond System, which has chloride concentrations ranging between 66.0 and 84.8 mg/L.
- Wells MW-DP3, MW-91-2, MW-75, and MW-16-6 upgradient of Upstream Raise 91 and downgradient/side-gradient to the plant and Extended Basin have chloride concentrations between 1.1 and 45.0 mg/L.

The chloride concentrations in the Extended Basin, nearby groundwater, and groundwater further downgradient of the Extended Basin are considerably above concentrations in MW-96, a background well for the plant that is side-gradient to the Extended Basin. Chloride concentrations at MW-96 range between 4.2 and 7.8 mg/L.

Variations in screened lithology and preferential flow paths in the glacial till may explain why some wells downgradient from the Extended Basin have elevated chloride concentrations while other wells (MW-DP3, MW-91-2, MW-75, and MW-16-6) have chloride concentrations more similar to MW-96.

It should be reiterated that inter-well statistical analyses are not recommended in this situation due to spatial variability and historical impacts and are included for discussion purposes only.

5.4.2 Appendix IV Parameters

To date, the Appendix IV parameters that are required as part of an assessment monitoring program under 40 CFR 257.95 have been collected solely as part of the initial baseline collection period described in 40 CFR 257.94(b), and approximately once annually for ongoing confirmation. Between 11 and 16 samples have been analyzed for each Appendix IV parameter for each Upstream Raise 91 groundwater monitoring well (through April 2020).

Results of the Appendix IV parameters in samples collected from monitoring network wells for Upstream Raise 91 are provided in Appendix C-1. In the event of a transition to assessment monitoring, a site-specific Ground Water

Protection Standard (GWPS) would be established for the detected Appendix IV parameters in accordance with 40 CFR 257.95(d)(2) and 40 CFR 257.95(h). For informational purposes only, confidence intervals were constructed using the non-site-specific GWPS detailed in 40 CFR 257.95(h)(1) and 40 CFR 257.95(h)(2) and are provided in Appendix C9.

Per the Unified Guidance, “A confidence interval is an estimated concentration or measurement range intended to contain a given statistical characteristic of the population form which the sample is drawn. When using a lower confidence interval on the mean, median, or upper percentile, an SSI occurs whenever the lower edge of the confidence interval range exceeds the GWPS (USEPA 2009).” Further, the Unified Guidance notes that. “By requiring that a lower confidence limit be used as the basis of comparison, the statistical test will account for data variability and ensure that the apparent violation is unlikely to have occurred by chance…Where the confidence interval straddles the limit, the test results are inconclusive (USEPA 2009).”

Based on the preliminary analyses of confidence intervals (Appendix C-9), no statistically significant levels of Appendix IV parameters would be identified for the current dataset, except for lithium. Lithium has consistently been detected at both the upgradient and downgradient monitoring wells at concentrations higher than the non-site-specific limit provided in 40 CFR 257.95(h)(2).

If assessment monitoring is initiated, a site-specific GWPS would be developed for lithium at CCS. Based on the concentrations of lithium in upgradient wells, a comparison of the downgradient concentrations to a site-specific GWPS would likely indicate that current concentrations are not statistically significant. It should be reiterated that these analyses are for information only and to-date a statistically robust comparative approach for determining statistically significant levels of Appendix IV parameters has not been developed. In addition, in the event of entering assessment monitoring, site-specific GWPS would be established for each parameter, which could vary from the non-site specific GWPS (see 40 CFR 257.95(h)).

6.0 LINER DESIGN SPECIFICATIONS AND CQA DOCUMENTATION – 257.71(D)(1)(I)(C)

As part of the application documentation, 40 CFR 257.71(d)(1)(i)(C) requires “Documentation of the design specifications for any engineered liner components, as well as all data and analyses the owner or operator of the CCR surface impoundment relied on when determining that the materials are suitable for use and that the construction of the liner is of good quality and in-line with proven and accepted engineering practices.”

The liner system in Upstream Raise 91 was constructed with an upper component consisting of high-density polyethylene (HDPE) geomembrane having a thickness of 40 mils (0.040 inches) and a lower component consisting of a compacted soil layer at least two feet thick with a hydraulic conductivity less than $1x10^{-7}$ centimeters per second (cm/sec). Construction Quality Assurance (CQA) monitoring was performed during installation of the Upstream Raise 91 composite liner system in 1992. Both the low-permeability soil layer and geomembrane layer were monitored as part of these CQA programs. The CQA report for Upstream Raise 91 (referred to as Ash Pond 91 in the report) is included as Appendix D-1 (CPA 1993) and applicable CQA documentation is provided below.

An additional 7 acres of composite liner was installed in the southeast corner of Upstream Raise 91 and in the area between Upstream Raise 91 and the Upstream Raise 92 in 2016 (Figure 27). Prior to composite liner construction, these areas were outside of the Upstream Raise 91 and Upstream Raise 92 CCR deposition footprint. This additional liner completes a continuous composite-lined area between Upstream Raise 91 and

Upstream Raise 92. The composite liner system installed in 2016 consists of (from bottom to top): Geosynthetic Clay Liner (GCL) and 60-mil HDPE liner. Typical west-east and south-north cross sections through Upstream Raise 91 are shown on Figure 3 along with details of the existing composite liners.

6.1 Native Soil Below the Composite Liner

As described in Section 4.1.3, native soils underlying the composite liner systems are characterized by hydraulic conductivity values ranging from $4.6x10^{-8}$ cm/sec to $1.8x10^{-6}$ cm/sec, with a geometric mean of $1.9x10^{-7}$ cm/sec. These near-surface native soils with relatively low hydraulic conductivity provide added protection of groundwater beneath the composite liner system for Upstream Raise 91.

6.2 Compacted Low-Permeability Soil Layers

CQA data obtained during installation of the composite liner systems included detailed information about the actual hydraulic conductivity of the low-permeability soil layers. 170 falling-head permeability tests were conducted on Shelby tube samples taken from the low-permeability soil layer for Upstream Raise 91. The hydraulic conductivity from these tests ranged from approximately $5x10^{-9}$ cm/sec to $1x10^{-7}$ cm/sec with a geometric mean hydraulic conductivity of $1.7x10^{-8}$ cm/sec. Summary tables of falling-head permeability tests conducted on Shelby tube samples taken from the low-permeability soil layer for Upstream Raise 91 (CPA 1993) are included in Appendix D2.

CQA data obtained during installation of the composite liner systems also included detailed information about the actual thickness of the low-permeability soil layers. Golder evaluated the actual thickness of the low-permeability soil layer for Upstream Raise 91 by comparing topographic surveys conducted immediately before and immediately after installation of the low-permeability soil layer (CPA 1993). The thickness of the low-permeability soil layer ranged between approximately 2 and 4.5 feet with an average thickness of 2.4 feet.

6.3 Geomembrane

CQA data obtained during installation of the composite liner systems included detailed information about the strength of the 40-mil HDPE geomembrane materials. The tests were performed on geomembrane samples either taken from rolls that were delivered to the site or on destructive geomembrane seam samples taken during installation. All tests (manufacturer quality control reports, laboratory conformance testing, and laboratory seam strength testing of field-welded seams) met or exceeded the requirements of the geomembrane liner specifications. The average results from these tests are shown in Table 5 and Table 6. Summary tables of geomembrane properties from manufacturer quality control certificates, laboratory conformance testing, and laboratory seam strength testing of field welded seams are included in Appendix D-3 for Upstream Raise 91 (CPA 1993).

Table 5: Geomembrane Roll Quality Control and Conformance Testing Results

Property	Units	Test Method	Upstream Raise 91 Average	40-mil HDPE Industry Standard GRI GM13 (GSI 2019b)
Thickness	mils	ASTM D1593	44	40 (nominal)
Yield Strength	pounds per inch	ASTM D638 ASTM D6693	121	84
Break Strength	pounds per inch	ASTM D638 ASTM D6693	220	152
Tear Resistance	pounds	ASTM D1004	37	28
Puncture Resistance	pounds	FTMS 101C 2065 ASTM D4833	86	72

Table 6: Geomembrane Field Seam Destructive Testing Results

Property	Units	Test Method	Upstream Raise 91 Average	40-mil HDPE Industry Standard GRI GM19a (GSI 2017)
Seam Shear Strength	pounds per inch	ASTM D638	127	80
Seam Peel Strength	pounds per inch	ASTM D638	86	60

The information pertaining to the actual strength of the 40-mil HDPE geomembrane materials is used in Section 6.4 to help assess the adequacy of 40-mil HDPE geomembrane to withstand the anticipated stresses on the composite liner system for Upstream Raise 91.

6.4 Geomembrane Integrity

The demonstrated integrity of the geomembrane materials and field seams produced for the Upstream Raise 91 (formerly referred to as Ash Pond 91) composite liner system is described in Sections 6.4.1, 6.4.2, and 6.4.3.

6.4.1 Minimum Geomembrane Properties for Survivability

Koerner (2012) provides guidance for the selection of minimum geomembrane properties for installation survivability, which refers to the ability of the geomembrane to survive the packaging, transportation, handling, unloading, storage, and installation processes. More severe installation conditions tend to require a higher degree of survivability; the required degree of survivability for the Upstream Raise 91 composite liner system would be categorized as Medium to High due to the machine-graded subgrade and relatively high loads. The minimum properties for installation survivability are summarized in Table 7 and compared against actual average properties for geomembrane materials used in the composite liner system for Upstream Raise 91.

Table 7: Comparison of Geomembrane Properties for Installation Survivability

Property	Required Degree of Installation Survivability				Upstream Raise 91 Average
	Low[1]	Medium[2]	High[3]	Very High[4]	
Thickness (ASTM D1593)	25 mil	30 mil	35 mil	40 mil	44 mil
Tensile Strength	52 pounds per inch (ASTM D882)	66 pounds per inch (ASTM D882)	81 pounds per inch (ASTM D882)	96 pounds per inch (ASTM D882)	121 pounds per inch (ASTM D638)
Tear Resistance (ASTM D1004)	7 pounds	10 pounds	15 pounds	20 pounds	37 pounds
Puncture Resistance	25 pounds (ASTM D4833)	32 pounds (ASTM D4833)	38 pounds (ASTM D4833)	45 pounds (ASTM D4833)	86 pounds (99 to 116 pounds[5]) (FTMS 101C 2065)

1. "Low" refers to careful hand placement on very uniform well-graded subgrade with light loads of a static nature, typical of vapor barriers beneath building floor slabs (Koerner 2012).

2. "Medium" refers to hand or machine placement on smooth, machine-graded subgrade with medium load, typical of canal liners (Koerner 2012).

3. "High" refers to hand or machine placement on machine-graded subgrade of poor texture with high loads, typical of landfill liners and covers (Koerner 2012).

4. "Very High" refers to hand or machine placement on machine-graded subgrade of very poor texture with high loads, typical of liners for heap leach pads and construction/demolition wastes (Koerner 2012).

5. Values determined from FTMS 101C 2065 are typically 15 to 35 percent lower than values determined from ASTM D4833 (Scheirs 2009).

Based on the information presented in Table 7 the geomembrane components of the composite liner system for Upstream Raise 91 exceeds even the Very High survivability requirements, which would be applicable to more severe installation conditions than those that existed during construction of Upstream Raise 91. This provides confidence that the geomembrane components were robust enough to be delivered, handled, and installed without damage.

6.4.2 Geomembrane Material Properties

The material strength properties for the geomembrane used in the composite liner system for Upstream Raise 91 is compared with the required material strength properties (based on current specifications) for various geomembranes types and thicknesses that are acceptable under the CCR Rule in Table 8.

Table 8: Comparison of Geomembrane Material Properties

Material	Yield Strength	Yield Elongation	Break Strength	Break Elongation	Tear Resistance	Puncture Resistance
	ASTM D638	ASTM D638	ASTM D638	ASTM D638	ASTM D1004	FTMS 101C 2065
Upstream Raise 91 40-mil HDPE (average)	121 pounds per inch (actual)	18% (actual)	220 pounds per inch (actual)	818% (actual)	37 pounds (actual)	86 pounds (actual) (99 to 116 pounds [1])
Material	**ASTM D6693**	**ASTM D6693**	**ASTM D6693**	**ASTM D6693**	**ASTM D1004**	**ASTM D4833**
40-mil HDPE GRI GM13 (GSI 2019b)	84 pounds per inch (minimum)	12% (minimum)	152 pounds per inch (minimum)	700% (minimum)	28 pounds (minimum)	72 pounds (minimum)
60-mil HDPE (smooth) GRI GM13 (GSI 2019b)	126 pounds per inch (minimum)	12% (minimum)	228 pounds per inch (minimum)	700% (minimum)	42 pounds (minimum)	108 pounds (minimum)
60-mil HDPE (textured) GRI GM13 (GSI 2019b)	126 pounds per inch (minimum)	12% (minimum)	90 pounds per inch (minimum)	100% (minimum)	42 pounds (minimum)	90 pounds (minimum)
30-mil LLDPE GRI GM17 (GSI 2019a)	None	None	114 pounds per inch	800% (minimum)	16 pounds (minimum)	42 pounds (minimum)
30-mil fPP GRI GM18 (GSI 2015)	None	None	60 pounds per inch (minimum)	700% (minimum)	10 pounds (minimum)	25 pounds (minimum)
Material	**ASTM D882**	**ASTM D882**	**ASTM D882**	**ASTM D882**	**ASTM D1004**	**None**
30-mil PVC ASTM D7176	None	None	73 pounds per inch (minimum)	380% (minimum)	8 pounds (minimum)	None

1. Actual average value increased by 15 to 35 percent for comparison against puncture resistance determined from ASTM D4833 (Scheirs 2009).

Based on the comparisons shown in Table 8, in all cases, the actual geomembrane property averages for Upstream Raise 91 exceeded the specified values for 30-mil LLDPE (linear low density polyethylene), 30-mil fPP (flexible polypropylene), and 30-mil PVC, all of which are accepted as the upper component in a composite liner system under 40 CFR 257.71(a)(1)(ii). Additionally, the actual geomembrane property averages for Upstream Raise 91 exceeded the requirements for 40-mil HDPE geomembrane and are comparable to the requirements for 60-mil HDPE geomembrane (smooth and textured). Therefore, the yield stress, yield elongation, break strength, break elongation, tear resistance, and puncture resistance for the 40-mil geomembrane materials used for Upstream Raise 91 are superior to those specified for materials that could be used in composite liner systems under the CCR Rule.

Design calculations can be used to evaluate the strength of a geomembrane with a given thickness and material composition against the range of stresses that could be imposed. Koerner (2012) presents an equation that can be used to determine the minimum geomembrane thickness, t, that is needed to resist the estimated tensile forces introduced by subsurface deformation that may be experienced during the geomembrane's service lifetime. The inputs to the equation are as follows:

- Normal stress on the composite liner system, σ_n, which results from the weight of the CCRs contained in the surface impoundment. For the most conservative application of the equation, σ_n is the product of the maximum height of the CCR deposit, H, and the unit weight of the CCRs, ɣ.
- Distance of mobilized geomembrane deformation, X. A value of 2 inches is appropriate for relatively high normal stress conditions, like in the Upstream Raise 91 composite liner system (Koerner 2012).
- Angle of shearing resistance between the geomembrane and the material overlying the geomembrane, δ_U.
- Angle of shearing resistance between the geomembrane and the material underlying the geomembrane, δ_L.
- Allowable shear stress for geomembrane, σ_{allow}. For purposes of this calculation, allowable shear stress is taken as the average yield strength (refer to Table 8) divided by the geomembrane thickness.
- Deformation angle mobilizing the tension in the geomembrane, β.

The equation for minimum geomembrane thickness is as follows:

$$t = \frac{\sigma_n \, X \, (tan \, \delta_U + tan \, \delta_L)}{\sigma_{allow} \, (cos \, \beta - sin \, \beta \, tan \, \delta_L)}$$

Based on consolidation analyses completed by Golder along Cross Sections B, and D through Upstream Raise 91 (refer to Appendix B-2), the maximum strain that the geomembrane component of the composite liner systems would be expected to experience is less than 1 percent. The relatively homogeneous near-surface soils, gradual changes in stratum thickness and impoundment geometry, and slow rate of CCR loading contribute to these relatively low expected strain levels. As a result, the deformation angle mobilizing the tension in the geomembrane, β, is estimated to be no greater than 5 degrees.

The angle of shearing resistance between the geomembrane and the sand overlying the geomembrane, δ_U, is estimated as 17 degrees based on a best-fit of 128 interface friction tests between smooth HDPE and granular soil reported by the Geosynthetics Research Institute (GRI 2005). The angle of shearing resistance between the geomembrane and the clay underlying the geomembrane, δ_L, has been evaluated through interface friction testing of site-specific materials and was determined to be 7 degrees (Appendix A-3, Golder 2016).

For the conservative case with the highest anticipated normal stresses at Upstream Raise 91 (H = 110 feet and ɣ = 100 pounds per cubic foot), the calculated minimum geomembrane thickness for Upstream Raise 91 is 0.022 inches (22 mils). The existing 40-mil HDPE geomembrane is sufficiently thick to withstand the anticipated stresses on the composite liner system.

6.4.3 Field Seaming

Extensive CQA observation and testing were conducted on the field seams between 40-mil geomembrane panels for the Upstream Raise 91 composite liner system during installation. The results of destructive testing on seam samples taken during installation indicate that the seam strengths met the project requirements. Table 9 compares the destructive test results for Upstream Raise 91 against industry-accepted seam strength requirements for 40-mil HDPE and for various geomembrane materials and thicknesses that are adequate for use as the upper component of a composite liner system under the CCR Rule.

Table 9: Comparison of Geomembrane Seam Strengths

Material	Test Method [1]	Shear Strength	Peel Strength
Upstream Raise 91 40-mil HDPE (average)	ASTM D638	127 pounds per inch (actual)	86 pounds per inch (actual)
40-mil HDPE GRI GM19a (GSI 2017)	ASTM D6392	80 pounds per inch (minimum)	60 pounds per inch (minimum)
60-mil HDPE GRI GM19a (GSI 2017)	ASTM D6392	120 pounds per inch (minimum)	91 pounds per inch (minimum)
30-mil LLDPE GRI GM19a (GSI 2017)	ASTM D6392	45 pounds per inch (minimum)	38 pounds per inch (minimum)
30-mil fPP GRI GM19a (GSI 2017)	ASTM D6392	25 pounds per inch (minimum)	20 pounds per inch (minimum)
30-mil PVC ASTM D7176	ASTM D882	58 pounds per inch (minimum)	15 pounds per inch (minimum)

1. ASTM D638 is applicable to tensile testing of various plastics and was commonly used for destructive testing of geomembrane seams when Upstream Raise 91 was constructed. Test methods like ASTM D6392 have since been developed specifically for testing geomembrane seams. The test procedures and the strengths measured by the two test methods are comparable.

Based on the comparisons shown in Table 9, the actual seam strength averages exceeded the required values for 30-mil LLDPE, 30-mil fPP, and 30-mil PVC, all of which are adequate to serve as the upper component in a composite liner system under 40 CFR 257.71(a)(1)(ii). Additionally, the actual seam shear strength and peel strength averages for Upstream Raise 91 exceeded the requirements for 40-mil HDPE geomembrane and are comparable to the strength requirements for 60-mil HDPE geomembrane.

In 2016, the composite liner system for Upstream Raise 91 was exposed in some locations to extend the lined area, and the 40-mil HDPE geomembrane component was joined by field seaming to new 60-mil HDPE geomembrane. CQA observations indicated excellent longevity of the 40-mil HDPE geomembrane, and

destructive samples of the resulting field seams were obtained and tested to verify that project requirements were being met. The test results are summarized in Table 10.

Table 10: Destructive Test Results for 2016 Field Seams

Specimen Identifier, Year, and Location	Shear Strength (ASTM D6392, Average of 5 Tests)	Shear Strength Requirement GRI GM-19a 40-mil HDPE	Upper Peel Strength (ASTM D6392, Average of 5 Tests)	Lower Peel Strength (ASTM D6392, Average of 5 Tests)	Peel Strength Requirement GRI GM-19a 40-mil HDPE
DS10 (2016) Upstream Raise 91	115 pounds per inch	80 pounds per inch (minimum)	103 pounds per inch	108 pounds per inch	60 pounds per inch (minimum)
DS15 (2016) Upstream Raise 91	114 pounds per inch	80 pounds per inch (minimum)	102 pounds per inch	94 pounds per inch	60 pounds per inch (minimum)
DS35 (2016) Upstream Raise 91	128 pounds per inch	80 pounds per inch (minimum)	101 pounds per inch	102 pounds per inch	60 pounds per inch (minimum)
DS36 (2016) Upstream Raise 91	145 pounds per inch	80 pounds per inch (minimum)	131 pounds per inch	124 pounds per inch	60 pounds per inch (minimum)

The CQA observations and the test results summarized in Table 10 confirm the integrity and longevity of the 40-mil HDPE geomembrane materials and the capability to produce quality welded seams, even 20 years or more after the 40-mil geomembrane was originally installed. In fact, the shear strengths and peel strengths are comparable to, and in most cases higher than, those required for 60-mil HDPE field seams under current industry standards.

6.5 Composite Liner Evaluations

In addition to the site-specific information provided above, several evaluations by industry experts have been performed comparing the performance of the CCR rule prescriptive composite liner with alternative composite liners like what exists at Upstream Raise 91 (thinner geomembrane layer). These reports were part of the work done to inform the alternative liner rulemaking in 2018 and 2019. Two of these reports are discussed below.

The Utility Solid Waste Activities Group (USWAG) engaged Gradient to prepare a performance evaluation methodology for composite and alternative surface impoundment liner systems (Appendix D-4, Gradient 2018). This report proposed a methodology for evaluating alternative liner systems and then presented performance evaluations for several liners. One scenario compares the hydraulic flux through a prescriptive composite liner (60-mil HDPE geomembrane underlain by a 2-foot soil layer with a hydraulic conductivity of $1x10^{-7}$ cm/sec) with an alternative composite liner (30-mil HDPE geomembrane underlain by a 2-foot soil layer with a hydraulic conductivity of $1x10^{-8}$ cm/sec). Even with modeling three times more defects in the 30-mil HDPE geomembrane, the modeled hydraulic flux through the alternative liner was estimated to be 54% of the hydraulic flux through the prescriptive composite liner. The alternative composite liner considered in this evaluation is very similar to the

composite liner system at Upstream Raise 91 which consists of a 40-mil HDPE geomembrane underlain by an average 2.4-foot soil layer with a hydraulic conductivity of $1.7x10^{-8}$ cm/sec (geometric mean).

The Electric Power Research Institute (EPRI) also evaluated the relative performance of liners for CCR surface impoundments (EPRI 2019). This report presents a proposed methodology for evaluating several alternative liner systems and the associated hydraulic flux through these liner systems. One scenario compares the hydraulic flux through the base case prescriptive composite liner (60-mil HDPE geomembrane underlain by a 2-foot soil layer with a hydraulic conductivity of $1x10^{-7}$ cm/sec) with an alternative composite liner (40-mil HDPE geomembrane underlain by a 2-foot soil layer with a hydraulic conductivity of $1x10^{-7}$ cm/sec). Similar to the Gradient (2018) report (Appendix D4), the evaluation assumed a higher defect density (2 times more defects) in the 40-mil HDPE geomembrane as compared to the 60-mil HDPE geomembrane. The evaluation did indicate "…that a thinner GM (geomembrane) will be more flexible, potentially resulting in better contact with the substrate, than a thicker GM of the same material, which can result in reduced leakage that - conceptually - offsets increased potential for perforations (defects)." Through modeling, the evaluation concluded that "All of the composite liners simulated in this evaluation performed similarly, with low (<0.13%) percentages of scenarios having maximum model-predicted concentrations higher than the lithium RSL or arsenic MCL. Even composite liners with a high defect density, representative of a thin (40-mil), non-federally compliant GM, achieved a level of protection comparable to the baseline composite scenario."

7.0 DIRECT TRANSPORT PATHWAY TO NEARBY SURFACE WATER – 257.71(D)(1)(I)(D)

For the application, 40 CFR 257.71(d)(1)(i)(D) states:

> "Facilities with CCR surface impoundment located on properties adjacent to a water body must demonstrate that there is no reasonable probability that a complete and direct transport pathway (i.e., not mediated by groundwater) can exist between the impoundment and any nearby water body. If the potential for such a pathway is identified, then the unit would not be eligible to submit a demonstration. If ongoing releases are identified, the owner or operator of the CCR unit must address these releases in accordance with 40 CFR 257.96(a)."

This language has been interpreted to require a demonstration that sub-surface releases do not have a potential to reach any nearby water body without being mediated by groundwater. The evaluation in this section is based on this interpretation.

Upstream Raise 91 was constructed as an above-grade impoundment with soil embankments and the minimum distance between the composite liner system and Samuelson Slough is approximately 300 feet laterally. Surface water drainage ditches exist on the west and south sides of Upstream Raise 91 and Upstream Raise 92 lies adjacent to the east side of the facility.

The foundation soils underlying Upstream Raise 91 consist of native soils (predominantly lean clay, fat clay, and sandy clay) and embankment fill materials sourced from nearby native soils. The downstream soil embankment slopes constructed in 1992 were compacted to a minimum of 93% standard Proctor density (CPA 1993). Based on historical site information and geotechnical testing during construction, the soils used in construction appear relatively consistent throughout the embankments, which are protected from erosion and deterioration by the establishment of a vegetative cover consisting of native grasses. The soils used in construction of Upstream

Raise 91 are relatively consistent and therefore a preferential flow path resulting in the transport of a release from the facility directly to Samuelson Slough is unlikely.

The composite liner system associated with Upstream Raise 91 extends from a low elevation of approximately 1898 feet in the northeast corner of the facility to an anchor trench surrounding the facility at a constant elevation of 1920 feet. The facility does not have openings in the liner system or other conduits that would allow water to be released and transported to nearby surface water without intersection with the uppermost water bearing zones of groundwater. As discussed above, the composite liner system is in direct contact with native soils (lean clay, fat clay, and sandy clay) and embankment fill materials sourced from nearby native soils. Potential leakage from the facility would be expected to migrate downward to the uppermost groundwater that lies approximately 5 to 15 feet below the bottom of the composite liner system (Appendix A-2, Golder 2018) before proceeding toward downgradient monitoring wells prior to reaching the nearest surface water.

As discussed in Section 2.4, the structural perimeter of CCR within Upstream Raise 91 is constructed using bottom ash and fly ash, while FGD material is contained in the center of the facility with a typical freeboard between 6 and 15 feet. Construction progresses in an upstream direction (toward the middle of the facility) and contact water from exterior fly ash slopes is contained within perimeter ditches inside the limits of the composite lined footprint. These ditches are generally dry, but during large storm events may manage between 1 and 2 feet of water before gravity draining into adjacent process water facilities. Due to the capacity of these ditches and the adjacent process water facilities, contact water is not able overtop the soil embankments and be transported offsite.

Based on the combination of sub-surface characteristics, the distance from the unit to the nearest water body, and operational and engineering controls associated with the water within the impoundment, there is no reasonable probability for a complete and direct pathway to a nearby water body that is not mediated by groundwater.

Any release that would be transported by groundwater would be detected by the installed groundwater monitoring well network. The monitoring wells are installed and screened at appropriate locations and depths to obtain groundwater from the uppermost water bearing zone between the facility and the nearest downgradient water body (Samuelson Slough). Cross Section D (Appendix B-2) shows the representative position of downgradient wells in relation to Upstream Raise 91 (e.g., Monitoring Well MW91-1 is representative of the location of the three wells downgradient of Upstream Raise 91). The number and spacing of the downgradient monitoring wells were selected based on the hydrogeologic conditions at the site and the areal extent of Upstream Raise 91 as discussed in Section 4.0 so as to identify groundwater impacts downstream of Upstream Raise 91 and upstream of Samuelson Slough.

1.0 INTRODUCTION

This report presents documentation and certification of the Location Restrictions Demonstration for the Upstream Raise 91 CCR Surface Impoundment (Upstream Raise 91) at Great River Energy's (GRE) Coal Creek Station (CCS). Upstream Raise 91 is an existing coal combustion residuals (CCR) surface impoundment. This report addresses the requirements of the United States Environmental Protection Agency's (EPA's) CCR rule (40 CFR 257.60 through 257.64, (EPA, 2015)). The location restrictions as defined in the CCR rule are summarized in the following sections.

1.1 Site Background

CCS is a coal-fired electric generation facility located in McLean County, North Dakota, approximately 10 miles northwest of Washburn, North Dakota. CCRs are managed in composite-lined surface impoundments and dry waste landfill facilities regulated and permitted by the North Dakota Department of Health (NDDH) in accordance with North Dakota Administrative Code (NDAC) Article 33-20, Solid Waste Management and Land Protection.

CCS has four CCR facilities that are within the purview of the EPA CCR rule (Figure 1):

- Drains Pond System CCR Surface Impoundment (Drains Pond System) is located in the south central portion of the plant site, northeast of the plant buildings.
- Upstream Raise 91 CCR Surface Impoundment (Upstream Raise 91) is located in the south central portion of the plant site, east of the plant buildings.
- Upstream Raise 92 CCR Surface Impoundment (Upstream Raise 92) is located in the southeast portion of the plant site, between Upstream Raise 91 and Southeast Section 16 CCR Landfill.
- Southeast Section 16 CCR Landfill (Southeast 16) is located in the southeast portion of the plant site, east of Upstream Raise 92.

2.0 LOCATION RESTRICTIONS

The location restrictions are found within the following sections of the Code of Federal Regulations:

- 40 CFR 257.60 – Placement above the uppermost aquifer
- 40 CFR 257.61 – Wetlands
- 40 CFR 257.62 – Fault areas
- 40 CFR 257.63 – Seismic impact zones
- 40 CFR 257.64 – Unstable areas

Per the CCR rule definitions, Upstream Raise 91 is considered an existing CCR surface impoundment and is subject to each of the location restriction requirements above.

3.0 PLACEMENT ABOVE THE UPPERMOST AQUIFER

Per 40 CFR 257.60, the base of existing and new CCR surface impoundments, new CCR landfills, and all lateral expansions must be no less than five feet (1.52 meters) above the uppermost aquifer, or a demonstration must be made that there will not be an intermittent, recurring, or sustained hydraulic connection between any portion of the base of the CCR unit and the uppermost aquifer due to normal fluctuations in groundwater elevations, including

fluctuations due to the seasonal high water table. The CCR rule defines the uppermost aquifer as the geologic formation nearest the natural ground surface that is an aquifer, as well as lower aquifers that are hydraulically interconnected with this aquifer within the facility's property boundary.

To provide support for the groundwater separation demonstration, groundwater levels were measured in the monitoring wells and piezometers surrounding Upstream Raise 91 from June 2017 through June 2018 (Figure 2). This was done to evaluate the normal fluctuations (including seasonal high water table) of groundwater elevation in the area of Upstream Raise 91.

Based on this measured data, the groundwater level fluctuated up to approximately 2.8 feet at individual wells/piezometers between June 2017 and June 2018. Groundwater contours were drawn based on the measured groundwater levels from October 2017 since groundwater levels were measured at additional site piezometers during this period, providing more detailed information for the development of groundwater contours. These groundwater contours were then compared to the as-built bottom of composite liner grades (Interstate Engineering, 1994). Figure 3 provides a visualization of the separation between the bottom of the composite liner (bottom of two feet of mechanically compacted clay liner) and the October 2017 groundwater contours. Most of the Upstream Raise 91 footprint has a separation between the bottom of the composite liner and groundwater greater than 5 feet. A small area in the northwest corner of the facility indicates a minimum separation of approximately 3.5 feet. From June 2017 through June 2018, the piezometer nearest this corner of Upstream Raise 91 (DP-B) showed groundwater elevations up to approximately 1.5 feet higher than the October 2017 readings. Therefore, the separation between the bottom of the composite liner and groundwater is anticipated to be greater than approximately 2.0 feet after considering potential site variations, including anticipated site seasonality based on the information collected.

Based on information acquired between June 2017 and June 2018, the base of the liner system at Upstream Raise 91 is above the upper limits of the uppermost aquifer and no intermittent, recurring, or sustained hydraulic connection between any portion of the base of the CCR unit and the uppermost aquifer exists.

4.0 WETLANDS

Per 40 CFR 257.61, existing and new CCR surface impoundments, new CCR landfills, and all lateral expansions must not be located in wetlands, unless a specific demonstration has been made by the owner or operator of a CCR unit ensuring that the unit will not degrade sensitive wetland ecosystems. Wetlands are areas that are inundated or saturated by surface or groundwater at a frequency and over a duration sufficient to support a prevalence of vegetation typically adapted for life in saturated soil conditions, and may include marshes, swamps, bogs, or other similar areas.

Upstream Raise 91 was constructed as an above-grade impoundment with grass covered perimeter earthen embankments and is located several hundred feet uphill of Samuelson Slough (closest surface water body). There are no visual indications suggesting the impoundment is located in wetlands. In addition, the NDDH, as part of the permit requirements of each facility, has previously accepted that Upstream Raise 91 is not located in wetlands (Golder, 2004).

Upstream Raise 91 is not located in wetlands.

5.0 FAULT AREAS

Per 40 CFR 257.62, new CCR landfills, new and existing CCR surface impoundments, and all lateral expansions must not be located within 200 feet of a fault (or the outermost damage zone of a fault) that has had displacement in Holocene time, unless a demonstration can be made that an alternative setback distance of less than 200 feet will not result in damage to the structural integrity of the unit. Holocene time is defined as the geological epoch which began at the end of the Pleistocene, roughly 11,700 years before the present, and continues to present time.

As evidence of being outside of fault areas, Figures 4 through 6 contain images derived from the United States Geological Survey's (USGS) Earthquake Hazards Program's U.S. Quaternary Faults and Folds Database. An overall map of the known faults in the contiguous United States is shown in Figure 4, while Figure 5 focuses on North Dakota. No known quaternary faults are located in the state of North Dakota. Further, Figure 6 provides the 2018 national earthquake probability map. North Dakota as a whole is predicted to have a less than 1% chance of potentially minor-damage ground shaking in 2018 (Petersen, et al., 2018).

Upstream Raise 91 is not located within 200 feet of a fault (or the outermost damage zone of a fault) that has had displacement in Holocene time.

6.0 SEISMIC IMPACT ZONES

Per 40 CFR 257.63, new CCR landfills, new and existing CCR surface impoundments, and all lateral expansions must not be located in seismic impact zones, unless a demonstration is made that shows all structural components, including liner, leachate collection systems, and surface water control systems are designed to resist the maximum horizontal acceleration in lithified earth material from a probable earthquake at the site. A seismic impact zone is defined as an area having a 2% or greater probability that the maximum expected horizontal acceleration, expressed as a percentage of the earth's gravitational pull (g), will exceed 0.10 g in 50 years. Maximum horizontal acceleration in lithified earthen materials is defined as the maximum expected horizontal acceleration at the ground surface as depicted on a seismic hazard map, with a 98% or greater probability that the acceleration will not be exceeded in 50 years.

Figure 7 is a map prepared by the USGS (Petersen, et al., 2014) showing the nationwide 2% probability in 50 years of exceedance of peak ground acceleration. On the map, the majority of North Dakota, including CCS, is given a 2% probability of exceeding 0.02 g in 50 years, below the 0.10 g threshold for defining a seismic impact zone.

Upstream Raise 91 is not located in a seismic impact zone.

7.0 UNSTABLE AREAS

Per 40 CFR 257.64, new and existing CCR landfills, new and existing CCR surface impoundments, and all lateral expansions must not be located in unstable areas, unless a demonstration can be made that shows the structural components of the unit will not be disrupted. The rule defines an unstable area as a location that is susceptible to natural or human-induced events or forces capable of impairing the integrity of some or all of the structural components responsible for preventing releases from a CCR unit. Unstable areas can include poor foundation conditions, areas susceptible to mass movements, and karst terrains. Per the rule, structural components are any component used in the construction and operation of the unit that are necessary to ensure the integrity of the unit and to prevent a release, and can include liners, leachate collection systems, embankments, spillways, outlets, final covers, and inflow design flood control systems.

Per the rule, the following factors were considered in determining whether the facilities have been located within unstable areas:

- On-site or local soil conditions that may result in significant differential settlement;
- On-site or local geologic or geomorphologic features; and
- On-site or local human-made features or events (both surface and subsurface).

Potential indications of unstable areas are evaluated during the annual visual inspections required to satisfy 40 CFR Part 257.83. These inspections are specifically meant to assess hydraulic structures, upstream and downstream slopes, berm crests, and the toe of the facility to look for signs of structural weakness, differential settlement, or other conditions that could affect stability. No evidence of differential settlement or other indications of unstable areas has been observed at the facility during the annual inspections performed in 2015, 2016, 2017, and 2018 (Golder, 2016a) (Golder, 2017) (Golder, 2018) (2018 inspection report not yet issued).

An assessment of structural stability and slope stability was completed for Upstream Raise 91 in 2016 (Golder, 2016b). This assessment evaluated foundation conditions as well as overall mass movement of the facility and indicated that no structural stability deficiencies were identified.

7.1 Soil Conditions

Upstream Raise 91 is generally constructed over a glacial till layer consisting of sand and silty-clay soils. Glacial till varies in thickness from 20 feet to several hundred feet in the area of CCS. Silty-sand and sand lenses are present throughout the glacial till formation, which is underlain by poorly consolidated siltstone/sandstone bedrock (Barr, 1982) (CPA and UPA, 1989).

The foundation soils of Upstream Raise 91 consist of native soils (sandy and silty-clay) and embankment fill materials sourced from nearby native soils (sandy and silty clay). Upstream Raise 91 was cleaned out and relined in 1993. According to construction documents, the foundation materials were compacted to 93% standard Proctor density. Based on historic site information of CCRs and native soils, observations, and geotechnical testing, Upstream Raise 91 is not built over wet ash or other unsuitable materials and foundation soils are stable (CPA, 1993).

Foundation site soil conditions do not indicate that the facility is located in an unstable area susceptible to significant differential settlement. Additionally, the site facilities are routinely inspected for both state and federal regulatory requirements. The facility will continue to be inspected per state and federal regulatory requirements, and signs of significant differential settlement will be documented and corrected as needed.

7.2 Geologic and Geomorphologic Features

CCS and McLean County are situated at the eastern-most extent of the Williston Basin, a structural and sedimentary basin (USGS, 1999). The region is characterized by the presence of glacial drift, reaching thicknesses of several hundred feet, and overlying the Sentinel Butte Member, the source of commercially mined coal in the direct vicinity of CCS (Falkirk Mining Company, 1979). The Sentinel Butte Member is the highest strata of the Paleocene Fort Union Formation, overlying the Tongue River, Ludlow, and Cannonball Members (USGS, 1999). The Sentinel Butte Member is marked by drab-gray units, separating it from the lower Tongue River Member.

The site geology of CCS includes unconsolidated surficial deposits of the Coleharbor formation consisting of stratified and unstratified glacial drift. The near-surface materials are silty clay and sandy clay till with interbedded

sand lenses (CPA and UPA, 1989). Karst is not known to exist at CCS based on USGS information (USGS, 2004) or site historical information from site borings and test pits (see Figure 8).

7.3 Human-Made Features

Although commercial mining occurs in the vicinity of CCS, no prior mining has occurred within the footprint of the facility, or adjacent to the facility, that would undermine the stability of the facility.

No significant fills, excavations, or structures are present adjacent to the facilities.

Upstream Raise 91 is not located in an unstable area caused by human-made features.

8.0 CERTIFICATION

The undersigned attest to the completeness and accuracy of the above written Location Restrictions Demonstration and certify that the location of Upstream Raise 91 at CCS meets the requirements detailed in 40 CFR 257.60 through 257.64, summarized as follows:

- 40 CFR 257.60 – Placement above the uppermost aquifer
  - Based on information acquired between June 2017 and June 2018, the base of the liner system for Upstream Raise 91 is above the upper limits of the uppermost aquifer and no intermittent, recurring, or sustained hydraulic connection between any portion of the base of the CCR unit and the uppermost aquifer exists.
- 40 CFR 257.61 – Wetlands
  - Upstream Raise 91 is not located in wetlands.
- 40 CFR 257.62 – Fault areas
  - Upstream Raise 91 is not located within 200 feet of a fault (or the outermost damage zone of a fault) that has had displacement in Holocene time.
- 40 CFR 257.63 – Seismic impact zones
  - Upstream Raise 91 is not located in a seismic impact zone.
- 40 CFR 257.64 – Unstable areas
  - Upstream Raise 91 is not located in an unstable area.

FISSURES, TUBES, AND CAVES OVER 1,000 FT (300 M) LONG; 50 FT (15 M) TO OVER 250 FT (75 M) VERTICAL EXTENT

- In metamorphosed limestone, dolostone, and marble
- In moderately to steeply dipping beds of carbonate rock
- In gently dipping to flat-lying beds of carbonate rock
- In gently dipping to flat-lying beds of carbonate rock beneath an overburden of noncarbonate material 10 ft (3 m) to 200 ft (60 m) thick
- In moderately to steeply dipping beds of gypsum
- In gently dipping to flat-lying beds of gypsum

FISSURES, TUBES, AND CAVES GENERALLY LESS THAN 1,000 FT (300 M) LONG; 50 FT (15 M) OR LESS VERTICAL EXTENT

- In metamorphosed limestone, dolostone, and marble
- In crystalline, highly silicieous intensely folded cabonate rock
- In moderately to steeply dipping carbonate rock
- In gently dipping to flat-lying carbonate rock
- In gently dipping to flat-lying beds of carbonate rock beneath an overburden of noncarbonate material 10 ft (3 m) to 200 ft (60 m) thick
- In moderately to steeply dipping beds of gypsum
- In gently dipping to flat-lying beds of gypsum
- In gently dipping to flat-lying beds of gypsum beneath and overburden of nongypsiferous material 10 ft (3 m) to 200 ft (60 m) thick
- In carbonate zones in highly calcic granite (Alaska only)
- In moderately to steeply dipping beds of carbonate rock with a thin cover of glacial till and frost-derived residual soil (Alaska only)

FISSURES, TUBES, AND CAVES GENERALLY ABSENT; WHERE PRESENT IN SMALL ISOLATED AREAS, LESS THAN 50 FT (15 M) LONG; LESS THAN 10 FT (3 M) VERTICAL EXTENT

- In crystalline, highly silicieous intensely folded carbonate rock
- In moderately to steeply dipping beds of carbonate rock
- In gently dipping to flat-lying beds of carbonate rock

FEATURES ANALOGOUS TO KARST

- Fissures and voids present to a depth of 250 ft (75 m) or more in areas of subsidence from piping in thick unconsolidated material
- Fissures and voids present to a depth of 50 ft (15 m) in areas of subsidence from piping in thick, unconsolidated material
- Fissures, tubes, and tunnels present to a depth of 250 ft (75 m) or more in lava
- Fissures, tubes, and tunnels present to a depth of 50 ft (15 m) in lava

- Areas in which extensive historical susidence has occurred

Introduction

This data set was converted from a printed map to a digital GIS coverage to provide users with a citable national-scale karst data set to use for graphic and demonstration purposes until new, improved data are developed. These data may be served on the internet or distributed freely with proper citation. Because it has been converted to GIS format, this data can be easily projected, displayed and queried for multiple uses in GIS. The karst polygons of the original map were scanned from the stable base negatives of the original, vectorized, edited, and then attributed with unit descriptions. All of these processes potentially introduce small errors and distortions to the geography. The original map was produced at a scale of 1:7,500,000; this coverage is not as accurate and should be used for broad scale purposes only. It is not intended for any site-specific studies.

The following text is taken verbatim from the original map, which was printed front and back on a single sheet.

ENGINEERING ASPECTS OF KARST

By
William E. Davies

Distinctive surficial and subterranean features developed by solution of carbonate and other rocks and characterized by closed depressions, sinking streams, and cavern openings are commonly referred to as karst. The term was used first to describe the region of Carso in northeastern Italy and northern Yugoslavia, where solution landscape was studied in the 19th century. Originally the term defined surface features derived by solution of carbonate rocks, but subsequent use has broadened the definition to include sulfates, halides, and other soluble rocks. The term has also been extended also to cover interrelated forms derived by solution on the surface in the subsurface. A further expansion of the concept of karst was the introduction of the term "pseudokarst" to designate karstlike terrain produced by processes other than the dissolution of rocks (Bergar and Dubertret, 1975). When used in its broadest sense, the term encompasses many surface and subsurface conditions that give rise to problems in engineering geology. Most of these problems pertain to subterranean karst and pseudokarst features that affect foundations, tunnels, reservoir tightness, and diversion of surface drainage. Environmental aspects of karst lead to additional problems in engineering geology, especially in site selection. Subterranean openings may be the habitat of unique and, in some cases, endangered fauna. The openings are also conduits for water and refuse disposal from the surface or, in caves, for pollutants that can be carried for great distances. Many caves contain features of beauty and scientific interest that can be important esthetic factors in site selection for structures, transportation routes, and impoundments.

Although surface features of karst terrain (primarily sinkholes, solution valleys, and solution-sculptured rock ledges) are significant in engineering geology, they have been included on this map because of the additional complexity that would occur in classification and portrayal.

The systematic study of karst in the United States started with W. M. Davis' (1930) theory on the origin of caves by deep-seated solution. Bretz (1942) obtained data, from studies in flat-lying carbonate rocks in the Midwestern States that supported Davis' theory. After World War II, studies of karst in the United States became widespread beginning with investigations in the Appalachian Mountains. Based on these studies, many of which were in areas of folded rock, older theories were modified with emphasis on maximum solution activity in a zone directly beneath a uniform water table (Davies, 1960). Since 1948, the exploration of caves and studies of landforms in carbonate terrains have produced a vast amount of data on karst. Reports of these explorations and studies have been primary sources in compiling this map on the subterranean aspects of engineering geology of karst and pseudokarst. In addition, published logs of borings were used. Much of the information on the Eastern United States, principally for the Appalachian Mountains and Plateau, is from field observations.

The small scale of the map and the limited data on openings, other than caves, in soluble rocks restrict the use of the map to the most general types of planning and as a guide to areas where subterranean karst and pseudokarst features occur. The map cannot be used either for specific site selection or as a substitute for field examination in planning and site development. Because cartographic license was taken to portray the features at the small scale of this map, enlargement can lead to gross errors in location of the data presented.

Subterranean openings in karst range in size from minute voids to large caverns. Most of the openings are formed by solution processes along fractures, joints, and bedding planes. Caves and related solution features are common in most carbonate and gypsum terrains in the United States, except in the area formerly covered by Pleistocene ice sheets (Davies and LeGrand, 1972). The southward advance of these ice sheets covered New England, New York, northeastern and northwestern Pennsylvania, most of the States bordering the Great Lakes, and much of the area north of the Missouri River. Karst features in the formerly glaciated area are covered by glacial drift, and most caves and fissure openings have been eroded away or filled. The caves and open fissures that remain generally have less than 1,000 ft (300 m) each of passages large enough to be traversed by humans.

South of the formerly glaciated area, caves, open joints, fissures, and other subterranean karst features are present in most soluble rocks. In general, both the number and size of solution features increase inversely with latitude. In addition, the number and size also vary according to the age and structure of the soluble rock in which solution features develop. Solution features in folded rocks are subordinate to those in nondeformed rocks; those in rocks older than Mississippian are subordinate to those in Mississippian and younger rocks. These are broad generalizations, and local exceptions exist. However, these generalizations can be used as a hasty estimate of karst conditions.

Most caves consist of a series of passages on one level. Some caves have multiple levels of passages that extend vertically as much as 300 ft (90 m). The levels are generally connected by shafts or large galleries. Most passages are less than 10 ft (3 m) high and less than 10 ft (3 m) wide. Maximum size of passages is about 100 ft (30 m) in height and width. In many caves, passages expand into galleries or rooms that are 30 to 200 ft (9 to 60 m) long and wide and up to 150 ft (45 m) high. The largest known solution opening in the United States is in Carlsbad Caverns, New Mexico, where a T-shaped room is 1,800 ft (550 m) long in one section, 1,100 ft (330 m) long in the other section, 255 ft (77 m) high, and up to 300 ft (90 m) wide.

Shafts are present in multiple-level caves and in some single-level caves. The deepest shafts are about 1,000 ft (300 m) deep, but in most caves they are less than 300 ft (90 m) deep. Most shafts are 30 ft (10 m) or less wide. In multiple-level caves, shafts connect levels; in other caves, the shafts are pits with no apparent connection at the base. Shafts are irregular in shape; some resemble funnels, and others are shaped like cylinders. Dome pits are cylindrical shafts that develop upward from a passage towards the surface of the Earth. Dome pits are up to 50 ft (15 m) wide and extend upward for as much as 150 ft (45 m). Their walls are uniform. Dome pits are capped by a cover of carbonate rocks 10 to 50 ft (3 to 15 m) thick. In many domes, the caps have collapsed and left vertical-sided open pits.

Virginia, West Virginia, Kentucky, Tennessee, Alabama, Missouri, Texas, and New Mexico contain hundreds of caves, each of which has over a mile of passages. At least one cavern system in each of these States has 10 to more than 100 mi (16 to 160 km) of passages. The largest known system is Flint Ridge-Mammoth Cave in Kentucky (Brucker, 1979), with over 200 mi (320 km) of passageways in an area of 362 mi (902 km).

Solution tubes with openings as much as 1 ft (0.3 m) wide and irregular alignment occupy portions of the carbonate bedrock. In some cases, the tubes connect with caves. However, the tubes generally lack the systematic patterns that are common in development of cavern passages. These tubes apparently predate cavern development. Although most tubes are seldom longer than a few hundred feet, they are interconnected and commonly act as conduits for subsurface drainage. During freezing weather, water from tubes can cause large buildups of ice where excavations intersect the tubes. At other times, the tubes lead to flooding of excavations and leaks in reservoirs and contribute to weakening of retaining walls.

Fissures (also referred to as open joints) up to 1 ft (0.3 m) wide result from limited solution along joints, fractures, and bedding planes. Fissures occur in various attitudes from vertical to gently inclined and generally are in repetitive geometrical patterns or sets. Fissures form systems that may extend for several thousand feet horizontally and over 300 ft (90 m) vertically. Some fissures or parts of fissures are filled with consolidated clay-silt and clay-gravel that seal them. The seals, however, are altered in contact with water and can be removed by running water. Fissures are commonly conduits for subterranean streams. In addition, they can cause serious engineering problems, such as reservoir leakage and instability of cuts, bridge abutments, piers, and dam foundations and abutments.

The depth to which solution openings occur depends on relief in an area, thickness of soluble rock, and geologic structure. The configuration and depth of the water table, in some cases, are controlling factors. Ground water in karst terrain generally is found in existing openings that extend tens to hundreds of feet below the water table. In the mountainous areas of the Western United States, the known vertical extent of solution openings is as much as 1,100 ft (330 m). In the Eastern United States, where relief is less, the vertical extent is generally less than 400 ft (120 m), with a maximum of 650 ft (200 m). Beneath many broad river valleys, solution features in carbonate rocks are present to a depth of about 100 ft (30 m) in both the Eastern and Western United States.

Surface subsidence (sinkhole development) occurs most commonly in areas where ground-water conditions are altered by excessive pumping or by diversion of surface drainage. Subsidence generally involves weathered bedrock and soil that bridge caverns, subterranean galleries, and dome pits. The collapse is caused by loss of support resulting from the reduction of hydrostatic pressure of ground water, by sapping, and by piping. Most subsidence forms shallow, steep-sided depressions up to 100 ft (30 m) wide and up to 20 ft (6 m) deep. However, in Florida and central Alabama, recent subsidence has resulted in nearly vertical sided sinkholes up to 425 ft (130 m) wide and 150 ft (45 m) deep.

Areas of local subsidence caused by mining operations and regional subsidence caused by withdrawal of ground water and petroleum in thick, unconsolidated sediments have not been included on the map of subterranean aspects of engineering geology of karst and pseudokarst because natural processes are involved only in a subordinate way in development of these phenomena. The problems of these types of subsidence are complex, and the areas involved are so extensive that they are best treated as subjects for another map.

In the New England States, solution terrain is confined to crystalline limestones and marbles mainly in northeastern Maine, western Vermont, and western Massachusetts. Solution features in these areas are primarily narrow fissures generally less than 200 ft (60 m) long and less than 30 ft (10 m) deep. A few small caves are known in western Vermont and in the Berkshire Mountains of western Massachusetts. In eastern Vermont and much of Maine, carbonate rocks high in silica and other impurities' are commonly, yet incorrectly, referred to as limestone. Solution features are generally absent in these rocks.

In the Appalachian Highlands, three major groups of carbonate rocks are in the karst regions. The Great Valley, in the eastern part of the Highlands, from southeastern New York to central Alabama, is a lowland up to 26 mi (42 km) wide eroded across dolomite, limestone, and shale of Cambrian and Ordovician age. Regionally, and to some extend reflecting differences in degree of karst development, the Great Valley is designated from north to south as the Kittatinny, Lehigh, Lebanon, Cumberland, Hagerstown, Shenandoah, and Tennessee Valleys. All types of solution features are present in the Great Valley, with small caves and fissures in southeastern New York and like features increasing in size and numbers southward. From central Virginia southward, large caves with over 1 mi (1.6 km) of passages in each are common, and fissures extend hundreds of feet in length and over 100 ft (30 m) in depth. The major geologic units involved in karst development in the Great Valley are the Elbrook (Cambrian), Conococheague (Cambrian-Ordovician), Beekmantown (Ordovician), and their equivalents. All are folded with steep dips, and overturning is common along the east half of the lowland. Faults are numerous and some major fault zones extend over 200 mi (320 km). Active subsidence is prevalent throughout the Great Valley and is a result primarily of alteration of the water table. Generally, the subsidence involves the opening of shallow fissures and shafts up to 10 ft (3 m) in diameter in farmland through removal of soil and thin rock cover over fissures, shallow cavern passages, and small dome pits. More extensive subsidence is in progress in the vicinity of Allentown and Harrisburg, Pennsylvania, where numerous subsidence depressions up to 100 ft (30 m) in diameter have developed. In Staunton, Virginia, active subsidence from collapse of rocks and soil covering shallow caves and fissures was recorded as early as 1911. Subsidence in the Staunton area resulted from large-scale piping of sinkhole soils by leakage from settling basins and from drawdown of the water table. In central Alabama, steep-sided, water-filled sinks, up to 425 ft (130 m) wide and 150 ft (45 m) deep, have formed recently by collapse of weathered limestone and thick soils covering limestone.

In the area west of the Great Valley, a sequence of limestones in the Upper Silurian (Tonoloway) and the Lower Devonian (Helderberg Group) forms subordinate ridges in southeastern New York, central Pennsylvania, eastern West Virginia, and western Virginia. The rock is folded, and dips are steep. Karst features include fissures extending several hundred feet vertically and caves with up to 1 mi (1.6 km) of large passageways. Subsidence is uncommon, but the fissures and caves have caused problems in foundations and abutments of dams, in cuts because of unstable wedges, and in tunnels that encounter earth fills in solution cavities.

Along the western edge of the Valley and Ridge province of the Appalachian Highlands, several large basinlike lowlands underlain by Cambrian and Ordovician carbonate rocks occur. The lowlands are eroded across large anticlines with steep dips on the flanks and moderate to steep plunges along the axes of the anticlines. In the Nittany and Kishacoquillas Valleys of Pennsylvania, and some smaller valleys designated as "coves," numerous caves occur, each with passageways 1,000 to 5,000 ft (300 to 1,5'j0 m) long The passages generally are 100 ft (30 m) or less below the surface. Many act as subterranean feeders that carry runoff from adjacent ridges to a few points of resurgence. The resurgent points are large springs with a daily flow of up to 1 million gallons or more (4 million or more). Fissures are present but seldom exceed 200 ft (60 m) in depth. Subsidence is not common, but deep cuts and excavations are subject to uncontrollable flooding if major subterranean conduits are encountered. In Germany Valley, West Virginia, solution features, primarily multiple-level caves and fissures, extend to depths of 350 ft (105 m) or more. Drainage of most of this valley is by way of one large spring. Subsidence from collapse of sinkholes is common, and potential for subsidence exists over numerous dome pits above caves.

The Appalachian Plateau's province and adjacent parts of the Interior Plains in West Virginia, Kentucky, Tennessee, northern Alabama, and southern Indiana contain the most intensely developed karst areas in the United States. The karstic carbonate rocks are Mississippian in age and include the Greenbrier limestone (West Virginia) and the Golconda, Ste. Genevieve. St. Louis, and Warsaw limestones and their equivalents elsewhere. Caves generally contain 3,000 ft (900 m) or more of passageways. Multiple-level caves are not common, but some large cave systems, such as Flint Ridge-Mammoth Cave in Kentucky and Organ Cave in West Virginia, have a multitude of complex passageways at various elevations that extend in aggregate from 30 to over 200 miles (48 to over 320 km). Dome pits, common in many caves, are areas of potential collapse. Many of the caves are large subterranean drainageways that receive streams flowing from adjacent highlands. Cuts and excavations intersecting these caves are subject to inundation from over 1 million cubic ft (40,000 m³) of water stored in the subterranean reservoirs. Large sinkholes, up to 1 mi (1.6 km) wide and several hundred feet deep, are so numerous that the rims of many sinkholes intersect the rims of their neighbors. Suitable foundations for large structures are difficult to site. Deep cuts, mines, tunnels, and excavations commonly encounter deeply weathered rock and large volumes of weak soil filling cavern passages and fissures. Seasonal flooding is common from snow melt and from heavy rainfall that exceeds the infiltration capacity of sinkholes and the capacity of subterranean channels to carry the runoff. Subsidence in most of the area is not extensive except above the dome pits and along karst valleys in southern Indiana and in the Mammoth Cave plateau in Kentucky.

In the Southeastern United States, karst is extensive on the Coastal Plain in southern Alabama, Georgia, and Florida. The limestones in the karst area are primarily the Ocala Limestone and Jackson Formation of Eocene age and their equivalents. In the Dougherty Plain of southeastern Alabama and southern Georgia, the limestone has been weathered deeply, and in the southern part of the plain the limestone is covered by a residuum of sandy clay. In the northern part of the plain, only small areas of the limestone remain within the residuum. Subsidence occurs as broad, slowly developing, shallow sinkholes in the residuum. In Florida, subsidence is more extensive. In the northern half of the State, the limestone is covered by younger sand deposits that are locally over 100 ft (30 m) thick. In Polk County, subsidence has resulted in vertical-sided sinkholes up to 150 ft (45 m) deep and 425 ft (130 m) wide. The subsidence has engulfed several houses and resulted in large property losses to homeowners. The subsidence is related to alteration of ground-water levels in caverns and to collapse of the weathered carbonate rock that supports the surface deposits.

In the Southeastern United States, karst is extensive on the Coastal Plain in southern Alabama, Georgia, and Florida. The limestones in the karst area are primarily the Ocala Limestone and Jackson Formation of Eocene age and their equivalents. In the Dougherty Plain of southeastern Alabama and southern Georgia, the limestone has been weathered deeply, and in the southern part of the plain the limestone is covered by a residuum of sandy clay. In the northern part of the plain, only small areas of the limestone remain within the residuum. Subsidence occurs as broad, slowly developing, shallow sinkholes in the residuum. In Florida, subsidence is more extensive. In the northern half of the State, the limestone is covered by younger sand deposits that are locally over 100 ft (30 m) thick. In Polk County, subsidence has resulted in vertical-sided sinkholes up to 150 ft (45 m) deep and 425 ft (130 m) wide. The subsidence has engulfed several houses and resulted in large property losses to homeowners. The subsidence is related to alteration of ground-water levels in caverns and to collapse of the weathered carbonate rock that supports the surface deposits.

Cretaceous carbonate rocks of the Selma Group are extensive in central and western Alabama and northeastern Mississippi. These rocks show little alteration by solution, and open fissures, open joints, and caves are generally not present.

The Silurian limestones and dolomites (Niagaran) of northwestern Ohio and adjacent Indiana are buried beneath glacial drift. Only in northwestern Ohio, where the glacial deposits are less than 20 ft (6 m) thick, are there karst features large enough to cause problems in engineering geology. Caves, each generally with less than 1,000 ft (300 m) of passages, are present but not numerous. Fissures less than 100 ft (30 m) wide extend for hundreds of feet. Small areas of subsidence have been attributed to alteration of the water table by pumping processes in quarries several miles from the site of subsidence. Because of the flat terrain, excavations and cuts seldom are deep enough to encounter major karst features. In the vicinity of Sandusky, Ohio, and on some of the nearby islands in Lake Erie, beds of calcium sulfate expand and change because of weathering and may cause local problems in heaving.

Broad anticlines with gentle dips bring Ordovician limestones and dolomite to the surface in southwestern Ohio and north-central Kentucky. Small caves and numerous joint-controlled fissures occur. Subsidence is not common or extensive, but the fissures and caves that result contain a large volume of water that may flood excavations. Ordovician and Silurian carbonate rocks also are brought to the surface in a broad anticline in central Tennessee around Nashville. Karst conditions are similar to those in north-central Kentucky.

In the Lower Peninsula of Michigan, carbonate rocks are extensive but are buried deeply beneath glacial deposits. Silurian limestones along Lake Huron between Alpena and the Straits of Mackinac contain several large sinkholes up to 1 mi (1.6 km) long and 200 ft (60 m) deep. The sinkholes are interconnected by an extensive fissure system. Normally, the sinkholes are filled with water, but, over time, plugs in the fissure system fail and the lakes drain through the subterranean openings. Subsidence generally does not occur in the Lower Peninsula.

Ordovician limestones cover the south half of the Upper Peninsula of Michigan and extend through eastern and southern Wisconsin, eastern Iowa, and parts of southeastern Minnesota. Karstic features are poorly developed and consist of simple caves, each with less than 1,000 ft (300 m) of passageways and less than 50 ft (15 m) of vertical extent. Fissures developed along joint lines are in about the same size range as the caves. In the vicinity of Dubuque, Iowa, and extending into adjacent Wisconsin and Illinois, fissures several hundred feet long and more than 300 ft (90 m) deep have been encountered in lead-zinc mines. The fissures possibly are relict from older buried karst. Subsidence from karst features is rare, although subsidence over mines is extensive.

The Ozark Plateaus province and adjacent plains in Missouri and northern Arkansas have extensive karst areas. The Ozarks are a large regional structural dome with steep dips along the southern flank. The dome brings Cambrian and Ordovician limestones and dolomites to the surface. North and west of the dome are plains underlain by Mississippian carbonate rocks (Warsaw, St Louis, Ste. Genevieve, and equivalents). Within the Ozarks, caves, each with passages 1,000 ft (300 m) or more long, are common. The passages in most caves extend to a depth of less than 100 ft (30 m). Pits, formed by collapse into cavern shafts and dome pits, are common, and, in southern Missouri, active subsidence is extensive. Most of the pits are water filled. Fissures over 1,000 ft (300 m) long and more than 300 ft (90 m) deep are present in much of the area. Similar fissures are numerous in the lead-zinc mining region in southwestern Missouri and adjacent Oklahoma and Arkansas. Throughout the Ozarks, the caves and fissures give rise to serious problems in foundations and abutments of dams and with reservoir tightness, stability of bridge piers, and stability of cut slopes. The presence of large quantities of subterranean water is a problem in deep foundations.

The Niobrara Formation (Upper Cretaceous) and its equivalents are the most widespread carbonate rocks in western Kansas, eastern Nebraska, and southeastern South Dakota. The Niobrara is generally covered by more than 50 ft (15 m) of younger sediments. Small fissures, less than 1,000 ft (300 m) long and up to 100 ft (30 m) deep, are present, but they are not common and are generally irregularly spaced with 1,000 ft (300 m) or more of solid rock between fissures.

Salt beds in south-central and southwestern Kansas form karst areas. Fissures are extensive, with openings more than 1,000 ft (300 m) long and over 300 ft (90 m) deep. Throughout the saline rock, recent subsidence has resulted from natural causes, as well as from alteration of the water table by solution mining and open pit mining.

In western South Dakota and adjacent parts of Wyoming and Montana, Paleozoic and Cretaceous carbonate rocks, arched steeply upwards, encircle the structural dome that forms the Black Hills. Caves and open fissures are common in the Paleozoic carbonate rocks. A few caves contain many miles of passages but most of the cave passages and fissures in the Black Hills area only extend up to 3,000 ft (900 m) in length and are generally less than 150 ft (45 m) in depth. Closely spaced solution joints also are prevalent.

In western Oklahoma and in the eastern part of the Texas Panhandle, extensive areas of karstic gypsum occur. Small open fissures up to 50 ft (15 m) deep and 1,000 ft (300 m) long are present. Passages in caves in gypsum are generally of similar length and depth.

The Edwards Limestone (Cretaceous) in west-central Texas forms an extensive plateau. Large caves and fissures are present to a depth of 600 ft (180 m), and both fissure systems and passages of single caves commonly extend for more than 1 mi (1.6 km). Both the caves and fissures contain large quantities of water in their deeper parts.

Permian carbonate rocks in central and southern New Mexico contain numerous well-developed karst features. Caves are generally very large and contain miles of passages with a vertical extent of 1,000 ft (300 m) or more. Fissures are of similar size and are interconnected, forming networks that extend for several miles. Closely spaced open joints, enlarged by solution, and numerous small, near-surface solution tubes cause extensive trouble in reservoir tightness throughout this karst area.

In northern and central Arizona, the Kaibab Limestone (Lower Permian) and its equivalents are karstic. North of the Grand Canyon, subterranean openings are primarily widely spaced fissures up to 1,000 ft (300 m) long and 250 ft (75 m) or more deep. South of the Grand Canyon, the fissures are more closely spaced and a few shallow caves are present. East of Flagstaff, there is an area of open fissures. These fissures are over 300 ft (90 m) deep, up to 1,000 ft (300 m) long, and up to 3 ft (1 m) wide. They cut the Coconino Sandstone, as well as the Kaibab Limestone (Colton, 1938).

The Madison Limestone (Mississippian) lies under karst areas in western Montana and adjacent parts of Idaho and Wyoming. Passages in a single cave are commonly up to 2 mi (3.2 km) long. Open fissures up to 1,000 ft (300 m) long and shallow, open joint systems are also common. Fissures and cavern passages extend as much as 1,000 ft (300 m) deep. Large quantities of water are present in the lower parts of the fissures and in some of the deeper cavern passages. Relict karst features developed during times of disconformity at the top of the Mississippian are common in the Madison Limestone. Most of the relict features are solution tubes, caves, and small fissures that have been filled with younger deposits that are now lithified. Because of differences in materials, residual openings, and secondary solution, these features can give rise to foundation problems and leakage.

Karst features in Alaska are not well known. Most of these features are shallow, swalelike depressions developed in a thin cover of residual soil and glacial till that lies over intensely folded limestone. A few cave openings are in limestone bluffs, but most cave entrances are hidden by a cover of spalled rock fragments. Streams crossing limestone terrains commonly disappear into the soil mantle and resurge at contact with insoluble rocks bordering the limestone. No subsidence features have been reported in Alaska.

Pseudokarst conditions in the United States develop in areas of thick, unconsolidated sediments and are primary features in basalt lava. In addition, in Mississippi and Alabama. numerous subsidence features occur in unconsolidated silt, sand and gravel of the Coastal Plain; these subsidence features are analogous to karst features. The subsidence occurs as numerous shallow depressions that are generally less than 50 ft (15 m) deep and up to 1 mi (1.6 km) or more wide. The depressions occur in Miocene and Pliocene sediments 800 to 1,000 ft (240 to 300 m) or more thick. Oligocene carbonate rocks are present beneath these sediments. The origin of the depressions is not understood The depressions appear to be associated with poorly drained areas such as flat lowlands and elevated, dissected, higher erosion surfaces. The depressions apparently are confined to flat surfaces and are not present on slopes that bound the flat surfaces. Excavations in the depressions probably would encounter weak and unstable soil and would be subject to flooding.

The High Plains of western Texas and adjacent States contain numerous depressions, some of which are as much as 3 mi (4.8 km) long and up to 1 mi (1.6 km) wide. They vary from "buffalo wallows," 3 to 10 ft (1 to 3 m) deep, to steep-sided features as much as 250 ft (75 m) deep. The depressions are aligned along a series of major joints and apparently formed by piping and removal of fine-grained material along joint planes at depths greater than 250 ft (75 m). Deep excavations in the depressions encounter weak, unstable soils and are subject to flooding from ground water during occasional periods of high rainfall.

Pseudokarst features in late Cenozoic basalt lava fields are extensive in some regions of the west. The largest regions with this type of pseudokarst are in the Snake River area of Idaho, in part of the Columbia Basalt Plateau in Washington and Oregon, and in the lava fields of northeastern California. Smaller areas are in New Mexico, Arizona, Utah, Nevada, southern California and on the Seward Peninsula in Alaska. The pseudokarst features include lava tubes, fissures, open sinkholes, and caves formed by extrusion of the still-liquid portion of the lava. Subsurface solution of the bedrock and subsequent collapse are not involved in the formation of these features. Lava tubes, in the form of tunnels, are commonly 10 ft (3 m) in diameter, and some extend for several miles. Fissures are common but seldom extend for more than 1,000 ft (300 m). The fissures and lava tubes, in contrast to solution features, are not in geometrical sets but are generally parallel and extend in the direction of the flow of the lava. Fissures and lava tubes are generally near-surface features, but some are as much as 250 ft (75 m) deep. "Sinkholes" in lava generally lack the symmetry of those developed in solution terrain. Most lava sinks are commonly less than 100 ft (30 m) wide, but a few large sinks, notably in the Snake River area of Idaho, are as much as 1 mi (1.6 km) or more wide. Most of the lava sinks are irregular in shape and generally are shallow features (less than 30 ft (10 m) deep), although some are 150 ft (45 m) or more deep. Many of the sinks have near-vertical sides or overhangs. Lava pseudokarst features present problems in foundations, abutments, and reservoir tightness. In addition, the tubes and related permeable lava often contain large quantities of water that may lead to flooding and slope-stability problems in cuts and excavations.

Acknowledgments and gratitude are extended to Allen W. Hatheway, Cambridge, Massachusetts, for information and guidance on pseudokarst in lava, to the thousands of members of the National Speleological Society whose papers on caves and karst areas they explored are the basic sources used in compilation of this map, and to members of the U.S. Geological Survey and various State Geological Surveys for information they contributed and for technical review and advice on this map and text.

1.0 INTRODUCTION

1.1 Purpose

The “Disposal of Coal Combustion Residuals (CCR) from Electric Utilities rule” (40 Code of Federal Regulations (40 CFR) Part 257), effective October 19, 2015, requires that existing CCR surface impoundments meeting the requirements of §257.73(a) and §257.73(b) conduct initial and periodic:

- Hazard potential classification assessments in accordance with §257.73(a)(2),
- Structural stability assessments in accordance with §257.73(d), and
- Safety factor assessments in accordance with §257.73(e).

This report documents the hazard potential classification assessment, structural stability assessment, and safety factor assessment for Great River Energy’s (GRE’s) Coal Creek Station (CCS) Ash Pond 91 CCR Surface Impoundment (Ash Pond 91).

1.2 Site Background

CCS is located in McLean County, approximately 10 miles northwest of Washburn, North Dakota. Ash Pond 91 covers approximately 75 acres (lined area) and is used as a combined dewatering and storage facility for CCRs including fly ash, bottom ash, and flue-gas desulfurization (FGD) material.

Ash Pond 91 was originally part of the South Ash Pond. The South Ash Pond was divided into Ash Pond 91 and Ash Pond 92. Ash Pond 91 was deepened and a new composite liner consisting of a 2-foot thick clay and 40-mil high-density polyethylene (HDPE) liner was completed in 1993. The liner is overlain with 1 foot of sand, 1 foot of Pit Run gravel, and a drainage system with collection pipes that slope to the north side of the facility. The composite liners of the Upstream Raise CCR Surface Impoundment (Upstream Raise) and Ash Pond 91 are connected and CCR deposition in Ash Pond 91 will piggyback onto the west side of Upstream Raise.

1.3 Geological Conditions

Ash Pond 91 is generally constructed over a glacial till layer consisting of sandy and silty-clay soils. Glacial till varies in thickness from 20 feet to several hundred feet in the area of Coal Creek Station. Silty-sand and sand lenses are present throughout the glacial till formation, which is underlain by poorly consolidated siltstone/sandstone bedrock (Barr 1982; CPA and UPA 1989).

1.4 Dam Oversight/Permits

The North Dakota State Engineer regulates, controls, and supervises the construction and operation of dams within the state of North Dakota. All dams and impoundments that contain more than 50 acre-feet of water require a construction permit (NDCC 2003).

The North Dakota Department of Health (NDDH) Division of Waste Management is the environmental regulatory body for the CCR facilities at CCS. Ash Pond 91 is currently permitted with the North Dakota Department of Health (NDDH) under Permit Number 0033.

1.5 Previous Evaluations

The following evaluations were previously performed on Ash Pond 91 at CCS:

- Golder Associates Inc., Evaluation of Ash Pond 91 Berm Stability Report, Great River Energy Coal Creek Station, dated April 13, 2010
- Golder Associates Inc., Seismic Stability Evaluation Addendum to Evaluation of Ash Pond 92/SW Section 16 Stability and Evaluation of Ash Pond 91 Stability, Great River Energy Stanton Station, dated February 27, 2012
- Kleinfelder, Coal Ash Impoundment Site Assessment Final Report, Coal Creek Station, October 31, 2012

In this study, we have reviewed the previous analyses, modified the analyses as deemed appropriate, and added suitable cases to evaluate whether the impoundment meets the required safety factors in §257.73(e)(1)(i)-(iv).

2.0 HAZARD POTENTIAL CLASSIFICATION ASSESSMENT – §257.73(A)(2)

The CCR rules require conducting initial and periodic hazard potential classification assessments by a qualified professional engineer to document the hazard potential classification of CCR surface impoundments and the basis for the classifications. Hazard classifications include the following listed in §257.73(a)(2):

- High hazard potential CCR surface impoundment,
- Significant hazard potential CCR surface impoundment,
- Low hazard potential CCR surface impoundment.

These hazard classifications are defined under §257.53 as:

> **High hazard potential CCR surface impoundment** – means a diked surface impoundment where failure or mis-operation will probably cause loss of human life.
>
> **Significant hazard potential CCR surface impoundment** – means a diked surface impoundment where failure or mis-operation results in no probable loss of human life, but can cause economic loss, environmental damage, disruption of lifeline facilities, or impact other concerns.
>
> **Low hazard potential CCR surface impoundment** – means a diked surface impoundment where failure or mis-operation results in no probable loss of human life and low economic and/or environmental losses. Losses are principally limited to the surface impoundment owner's property.

2.1 Hazard Potential Classification Assessment

Based on the hazard classification definitions and review of the site and surroundings, Golder recommends Ash Pond 91 be categorized as a **Low Hazard Potential CCR Surface Impoundment**. This recommended designation is based on the following:

- The amount of impounded water is relatively small.
- There are no residences or occupied structures directly adjacent to the facility and loss of human life is not probable.
- Discharge of water or other materials contained within the impoundment is unlikely to have a significant environmental impact and is not likely to leave the owner's property. Samuelson Slough has significant volume to contain discharge from the impoundment and has a controlled discharge that can be closed in the event of a release.
- The economic impacts associated with a failure will primarily be to the owner's property.
- A USEPA consultant performed a site assessment of Coal Creek Station in 2011 under USEPA supervision. Following the USEPA dam hazard classification system, Ash Pond 91 was given a "Low Hazard" classification (Kleinfelder 2012).

2.2 Emergency Action Plan – §257.73(a)(3)

The CCR rules require the development of an Emergency Action Plan (EAP) for a CCR unit determined to be either a high hazard potential CCR surface impoundment or a significant hazard potential CCR impoundment. Ash Pond 91 has been categorized as a low hazard potential CCR surface impoundment and no EAP is required.

3.0 STRUCTURAL STABILITY ASSESSMENT – §257.73(D)(1)(I)-(VII)

The CCR rules (§257.73(d)(1)) require conducting initial and periodic structural stability assessments by a qualified professional engineer to "document whether the design, construction, operation, and maintenance of the CCR unit is consistent with recognized and generally accepted good engineering practices for the maximum volume of CCR and CCR wastewater that can be impounded therein."

3.1 Foundation – §257.73(d)(1)(i)

The location of Ash Pond 91 was originally characterized by Burns & McDonnell in 1973 and a hydrogeologic study was performed for CCS by Barr Engineering in 1982. Site geology, soils, and hydrology, including drainage and surface water flow, were examined during these prior studies to determine site suitability for disposal of CCRs.

The foundation soils of Ash Pond 91 consist of native soils (lean clay, fat clay, and sandy clay) and embankment fill materials sourced from nearby native soils (lean clay, fat clay, and sandy clay). Ash Pond 91 was cleaned out, deepened, and relined in 1993 (CPA 1993). According to construction documents, the foundation materials were compacted to 93% standard Proctor density.

Based on historic site information of CCRs and native soils, observations, and geotechnical testing, Ash Pond 91 is not built over wet ash or other unsuitable materials and foundation soils are stable.

3.2 Slope Protection – §257.73(d)(1)(ii)

The downstream slopes are divided into two sections, the soil embankment, and the Ash Pond 91 CCR slopes. Ash Pond 91 soil embankments are protected from erosion and deterioration by the establishment of a vegetative cover consisting of native grasses. The vegetative cover is inspected weekly for erosion, signs of seepage, animal burrows, sloughing, and woody vegetation that could affect the performance of the embankments.

Ash Pond 91 CCR slopes are protected from erosion and deterioration by a hardened fly ash surface. The fly ash slopes are inspected weekly for erosion, cracking, signs of seepage, animal burrows, sloughing, and woody vegetation that could affect the performance of the slopes.

The upstream slopes of the soil embankments are protected by a 2-foot thick layer of hardened fly ash. Active CCR upstream slopes are protected by a 6 to 15-foot high layer of trafficked bottom ash or other CCR material. The location of this layer of bottom ash changes as Ash Pond 91 increases in height and is maintained by GRE personnel on a weekly basis if deterioration is noted. Based on site experience and observations, the fly ash and bottom ash provide sufficient protection from deterioration due to wave action.

3.3 Dikes (Embankment) – §257.73(d)(1)(iii)

Embankments that are a part of Ash Pond 91 constructed in 1992 were compacted to a minimum of 93% standard Proctor density (CPA 1993). Based on historic site information and geotechnical testing during construction, the embankment soils are stable.

3.4 Vegetated Slopes – §257.73(d)(1)(iv)

Ash Pond 91 is inspected weekly. As part of these inspections, unusual or woody vegetative growth on slopes with final cover and soil embankments is documented. Vegetated slopes of Ash Pond 91 are re-seeded and mowed as required to maintain good vegetative growth and to limit woody vegetation from growing on the side slopes or near the toe of impoundments.

3.5 Spillways – §257.73(d)(1)(v)

Current inflows to the facility (besides precipitation) include hydraulically conveyed coal rejects material and passive drainage from the adjacent Upstream Raise CCR Surface Impoundment (Upstream Raise). Ash Pond 91 is designed to receive inflows from hydraulically conveyed FGD material and passive drainage from the Upstream Raise in the future. The design crest of the soil perimeter berms surrounding Ash Pond 91 is at an approximate elevation of 1922 feet, which is approximately 24 feet above surrounding topography, preventing stormwater run-on into Ash Pond 91.

Existing controls in place to monitor the water levels in Ash Pond 91 include weekly observations of water levels by CCS personnel, and daily observations by CCS operations personnel. Additional observations are noted by GRE employees familiar with site CCR units. After large storm events, CCS personnel evaluate site conditions, including impoundment water levels, and are able to adjust operations to maintain water levels below design maximum elevations. Should water levels within Ash Pond 91 reach above desired operating levels, GRE has operating procedures to lower gravity drain (decant) pipelines into the water to transfer water to the adjacent Drains Pond System CCR Surface Impoundment (Drains Pond System) facility. Contact water in perimeter ditches flows passively from the Ash Pond 91 to the Drains Pond System.

After 2016, Ash Pond 91 is designed to operate with a minimum freeboard of approximately 3 feet and a design freeboard of approximately 6-feet. A run-on analysis was performed as part of the inflow design flood control system plan (Golder 2016) indicating that Ash Pond 91 is operated with adequate freeboard to contain the 100-year, 24-hour storm event.

3.6 Hydraulic Structures – §257.73(d)(1)(vi)

Ash Pond 91 is designed to have an inflow pipe for depositing FGD material. The on-grade HDPE pipe will be 8 inches in diameter and will be periodically moved to different areas of the facility to achieve an even distribution of FGD material in the facility.

The outflows from Ash Pond 91 will consist of a series of gravity drainage pipes and culverts that transfer CCR conveyance water from the facility to the adjacent Drains Pond System.

No significant deterioration, deformation, distortion, bedding deficiencies, sedimentation, or debris were observed that may negatively affect the operation of the facility.

3.7 Downstream Slopes Adjacent to Water Body – §257.73(d)(1)(vii)

Samuelson Slough lies downstream of Ash Pond 91 (approximately 400 feet away); however, the outlet elevation of Samuelson Slough (and the site surface water drainages) are controlled and water cannot inundate the downstream toe or slopes of Ash Pond 91.

3.8 Structural Stability Deficiencies – §257.73(d)(2)

No structural stability deficiencies were identified during this assessment.

4.0 SAFETY FACTOR ASSESSMENT – §257.73(E)

The CCR rules require that safety factors need to be evaluated for the critical cross-section of each CCR facility under static and seismic loading for long-term maximum storage pool loading conditions and maximum surcharge pool loading conditions. Liquefaction potential analysis is only necessary when soil

sampling, construction documentation, or anecdotal evidence from personnel with knowledge about the facility, indicates that soils of the embankment are susceptible to liquefaction.

Slope stability analyses were performed using a limit-equilibrium-based commercial computer program, SLIDE v7.0 (Rocscience 2016). Factors of safety were computed for non-circular failure surfaces using Spencer's method for force and moment equilibrium. Global stability was analyzed, which evaluates the overall stability of a cross section through the entire facility.

4.1 Model Scenarios

Two types of loading conditions for the stability analyses were performed: static and seismic (pseudostatic analyses). For each of the two loading conditions, the critical cross section was modeled. Two impoundment pool loading scenarios were considered to evaluate the slope: long-term maximum storage pool loading condition and maximum surcharge pool loading condition. Four stability scenarios were analyzed (two static loading scenarios and two pseudostatic loading scenarios).

4.2 Slope Geometries and Critical Slope

A critical cross section for Ash Pond 91 was identified and used for the stability analyses. The critical cross section is anticipated to be the most susceptible to structural failure and was selected based on loading conditions, geometry of the slopes, and the soil profile.

The critical cross section for Ash Pond 91 is located across the north embankment (Figure 1) at the full height of the facility during operation as a surface impoundment. Subsequent to this phase of construction, Ash Pond 91 is planned to be dewatered, covered, and closed with CCR in place. The design crest of the soil perimeter berm at the critical section is at an approximate elevation of 1920 feet. The critical cross section has an approximately 100 foot wide crest at elevation 2004 feet and downstream slopes between 15% and 20% from elevation 2004 feet to approximately elevation 1920 feet (Figure 2). Based on existing topography, original downstream slopes generally have 3H:1V slopes down to perimeter drainage ditches with an elevation of approximately 1898 feet. Original soil perimeter berm upstream slopes have an approximate 3H:1V slope from this soil perimeter berm to the interior base elevation within the facility of 1900 feet.

4.3 Material Properties

Material properties (Table 1) were developed through Golder's site experience with onsite materials, laboratory tests completed on Coal Creek Station CCRs and onsite soils, reviews of technical literature, and Golder's professional judgment and experience with similar materials used for this slope stability analysis. Additional static materials properties information is included in Appendix A.

Table 1 Material Properties

Material	Wet Unit Weight (pcf)	Shear Strength Static Analysis		Shear Strength Pseudostatic Analysis		
		Effective Cohesion (psf)	Effective Friction Angle (degrees)	Undrained Cohesion (psf)	Undrained Friction Angle (degrees)	Undrained Shear Strength (psf)
Existing Natural Soil and Embankment Fill	127	500	19	165	14	NA
Clay Liner	122	500	19	NA	NA	1,600
Sand Layer	125	0	37	0	37	NA
Pit Run	125	420	34	420	34	NA
FGD Material	Varies	Appendix A	Appendix A	Appendix A	Appendix A	Appendix A
Bottom Ash	83	50	40	50	40	NA
Fly Ash	107	1610	32	1610	32	NA
Smooth Geomembrane – Clay Liner Interface	NA	200	7.5	200	7.5	NA
Smooth Geomembrane – Bottom Ash	NA	0	17	0	17	NA

4.3.1 Pseudostatic Material Properties

The material properties for each soil type included in the pseudostatic stability analysis of Ash Pond 91 are provided in Table 1 and were developed following the recommendations contained within Section 6.1 of *RCRA Subtitle D (258) Seismic Design Guidance for Municipal Solid Waste Landfill Facilities* (EPA 1995). Fine-grained soils (existing natural soil, embankment fill, and clay liner) were assigned strength parameters corresponding to 80% of the total stress (undrained) strength parameters.

- The existing natural soil and embankment fill were assigned strength parameters based on laboratory testing of those materials. The reduction of the strength parameters to 80% of the total stress strength parameters resulted in cohesion intercept of 165 pounds per square foot (psf) and a friction angle of 14 degrees.
- The clay liner was assigned an undrained shear strength of 1,600 psf based on literature values for CH material (NAVFAC 1996).
- The geosynthetic interface strength parameters were not modified (from the static stability material properties) for the pseudostatic stability analyses based on recommendations contained within Section 6.1.2 of *RCRA Subtitle D (258) Seismic Design Guidance for Municipal Solid Waste Landfill Facilities* (EPA 1995).
- Fly ash is a cemented material and is modeled with static shear strengths with no seismic reduction.
- FGD material properties were unchanged since undrained strengths are used for this material in both the static and seismic conditions.

Coarse-grained materials (i.e., sand, pit run, and bottom ash) are modeled with static shear strengths with no seismic reduction because they are not prone to developing excess pore pressure from the cyclic loading caused during seismic conditions. These materials are well compacted within the facility and are not likely to be saturated in the critical section evaluated.

4.4 Impoundment Pool Loading Conditions

Two different impoundment pool loading conditions were considered in these stability analyses:

- Long-term maximum storage pool loading condition
- Maximum surcharge pool loading condition

The depth of impounded water in Ash Pond 91 varies with time as more CCRs are deposited and as operational variables change (such as drainage pipe elevations). Based on facility operations in the adjacent Upstream Raise facility over the past 10 years, the maximum storage pool loading condition is anticipated to occur when the elevation of water within the impoundment is maintained at the approximate same elevation as FGD material, which equates to a freeboard to the surrounding embankments of approximately 9 feet. Slope stability was modeled at maximum facility height (when Ash Pond 91 is operating as an impoundment) with an embankment elevation of 2004 feet and a FGD material/water elevation of 1995 feet.

The maximum surcharge pool loading condition is conservatively modeled with a freeboard of zero feet (embankment elevation of 2004 feet and a water elevation of 2004 feet). In this scenario, the FGD material elevation within the facility remains at approximately 1995 feet. The likelihood of the water within Ash Pond 91 reaching an elevation of 2004 feet or overtopping the embankment is very low, based on the following reasoning:

- Primary design inflows to Ash Pond 91 are via the FGD pipeline from the plant. The FGD material inflow is actively managed per the operations plan and can be shut off at any time.
- Additional inflow may come from precipitation events; however, the only areas running into the impoundment pool include a small area on the upper surface of the facility (see Inflow Flood Control Plan, Golder 2016). Based on the Inflow Flood Control Plan, the maximum increase in elevation of Ash Pond 91 pool from a precipitation event is approximately 1 foot.

The operations plan discusses the operation and contingency plans associated with Ash Pond 91 (Golder 2015a).

4.5 Subsurface Water Conditions

Ash Pond 91 is lined with a composite geomembrane/clay liner. Readings from the piezometers and monitoring wells installed near Ash Pond 91 demonstrate that groundwater generally flows northeast under the facility toward Samuelson Slough and that groundwater elevations vary from approximately 1880 feet in the northeast corner of Ash Pond 91 to 1900 feet in the southwest corner of Ash Pond 91. Based on these data and the location of the critical section, the stability analyses were performed with a groundwater elevation of between approximately 1890 feet and 1895 feet.

4.6 Interior Impoundment Phreatic Surface

Seepage analyses were performed on Ash Pond 91 to determine the phreatic surface within the facility at the maximum impoundment elevation (FGD material elevation 1995 feet, Golder 2015b). The phreatic surface is shown in Figure 2 and was assumed to follow the bottom ash/FGD material interface for full height steady state conditions. Hydrostatic pore pressures were assumed below the phreatic surface as water is anticipated to drain relatively slowly through FGD materials toward perimeter drainage piping. After FGD material deposition ceases, the phreatic surface decreases in elevation as the FGD material consolidates and drains.

4.7 Seismic Loading Conditions

Coal Creek Station, located in central North Dakota, is in an area with low historic seismic activity. No earthquakes of Magnitude V (i.e., Moderate-Strong) or greater (Mercalli intensity scale) have occurred in North Dakota during historical times (USGS 2016).

4.7.1 Peak Ground Acceleration Determination

For the site location, the peak (bedrock) ground acceleration (PGA) with a 2% probability of exceedance in 50 years is between 0.02g (1g equals 32.2 ft/sec^2) and 0.04g using the *US Seismic Hazard 2014 Map* (USGS 2014) and the *US Seismic Hazard 2008 Map* (USGS 2008); for purposes of this analysis, the bedrock PGA was estimated to be 0.03g (Appendix B). The peak ground acceleration at Coal Creek Station was estimated to be 0.05g using the simplified analysis guidelines presented in Section 4.1.1 of the *RCRA Subtitle D (258) Seismic Design Guidance for Municipal Solid Waste Landfill Facilities* (EPA 1995, see Appendix B).

4.7.2 Horizontal Seismic Coefficient Determination

The horizontal seismic load coefficient (k_s), for use in the pseudostatic slope stability analysis, was determined using the procedures recommended in Section 6.2 of the *RCRA Subtitle D (258) Seismic Design Guidance for Municipal Solid Waste Landfill Facilities* (EPA 1995). Based on Step 2 of the Seismic Stability and Deformation and Analysis section of the guidance (Section 6.2), the maximum value of the horizontal seismic load coefficient may be safely determined as one-half of the peak ground acceleration (determined in Section 4.7.1). As a result, a horizontal seismic load coefficient of 0.025g (0.5 * 0.05g = 0.025g) was used in the pseudostatic analysis.

4.8 Liquefaction Potential

Soil liquefaction describes a phenomenon in which a saturated or partially saturated soil substantially loses strength and stiffness in response to an applied stress, usually earthquake shaking or other sudden change in stress condition, causing it to behave like a liquid. The phenomenon is most often observed in saturated, loose (low density or uncompacted), sandy soils. The foundation and embankment materials (existing

natural soils, embankment fill, and clay liner) of Ash Pond 91 are classified as either low or high plasticity clay.

In addition, an assessment of liquefaction potential was evaluated given the limited information about the site and in-situ testing of FGD material. The analysis of liquefaction potential is based partially on EPA's "Seismic Design Guidance for Municipal Solid Waste Landfill Facilities" published in 1995 (EPA 1995) and the evaluation of liquefaction resistance based on SPT values described by Youd and Idriss (2001). This method uses material SPT values, material unit weight, and expected ground motion for North Dakota (acceleration) to evaluate liquefaction potential. Based on a range of cyclic stress ratios (CSR) between 0.04 and 0.11 and corrected SPT blow counts of between 3 and 14 for FGD material, Ash Pond 91 is not anticipated to be susceptible to liquefaction due to low seismic stresses.

4.9 Stability Analysis Results

Slope stability analyses were performed under static and pseudostatic conditions for the critical section (Figure 3 and Figure 4). The results of the slope stability analyses are presented in Table 2. The results indicate that Ash Pond 91 slopes comply with the required safety factors per §257.73(e).

Table 2 Slope Stability Analyses Results

Loading Condition	Water Level	Required Factor of Safety	Calculated Factor of Safety	Figure for Stability Analysis Results
Static	Max Storage (el. 1995 ft)	1.50	1.59	3
	Max Surcharge (el. 2004 ft)	1.40	1.59	3
Pseudostatic	Max Storage (el. 1995 ft)	1.00	1.34	4
	Max Surcharge (el. 2004 ft)	1.00	1.34	4

5.0 CERTIFICATION

Based on the review of the information provided by GRE and on-site observations, we have classified the Coal Creek Station Ash Pond 91 CCR Surface Impoundment as a Low Hazard Potential CCR Surface Impoundment; additionally, no structural stability deficiencies were identified during this assessment. Calculated factors of safety through the critical cross sections in the surface impoundment embankments exceed the values listed in §257.73(e)(1)(i)-(iv).

The undersigned attest to the completeness and accuracy of this hazard potential classification, structural stability assessment, and safety factor assessment, and certify that the assessments meet the requirements of 40 CFR §257.73(a)(2), §257.73(a)(3), §257.73(d), and §257.73(e).

APPENDIX A
MATERIAL PROPERTIES

1.0 OBJECTIVE

Compile a list of material properties used in the engineering evaluation and indicate sources for all inputs.

2.0 MATERIALS

2.1 Existing Natural Soil and Embankment Fill

Existing natural soil and embankment fill properties were based on lab work performed by Golder on samples taken from the SW Section 16 area in 2001, 2008, and 2011. Soils on site are generally low plasticity clay (CL), but high plasticity clays (CH) are also present. Samples yielded an average dry unit weight of 105.1 pcf and an average moisture content of 20.7 %. Values of 105 pcf for the dry unit weight and 21 % for the moisture content were chosen resulting in a moist unit weight of approximately 127 pcf.

Two triaxial shear strength tests were performed from the SW Section 16 Shelby tube samples in 2001 (BH3 and BH6). Three additional triaxial tests were performed on existing natural soil near the River Water Holding Basin in 1981 (boreholes BR-1 and BR-2) and two triaxial tests were performed on existing natural soil near the cooling towers in 2008 (Tower 91 and Tower 92). Based on triaxial test information, a conservative strength envelope was developed for existing natural soil. The strength envelope is shown in Figure 1 and is defined by an effective cohesion of 500 psf and an effective friction angle of 19 degrees.

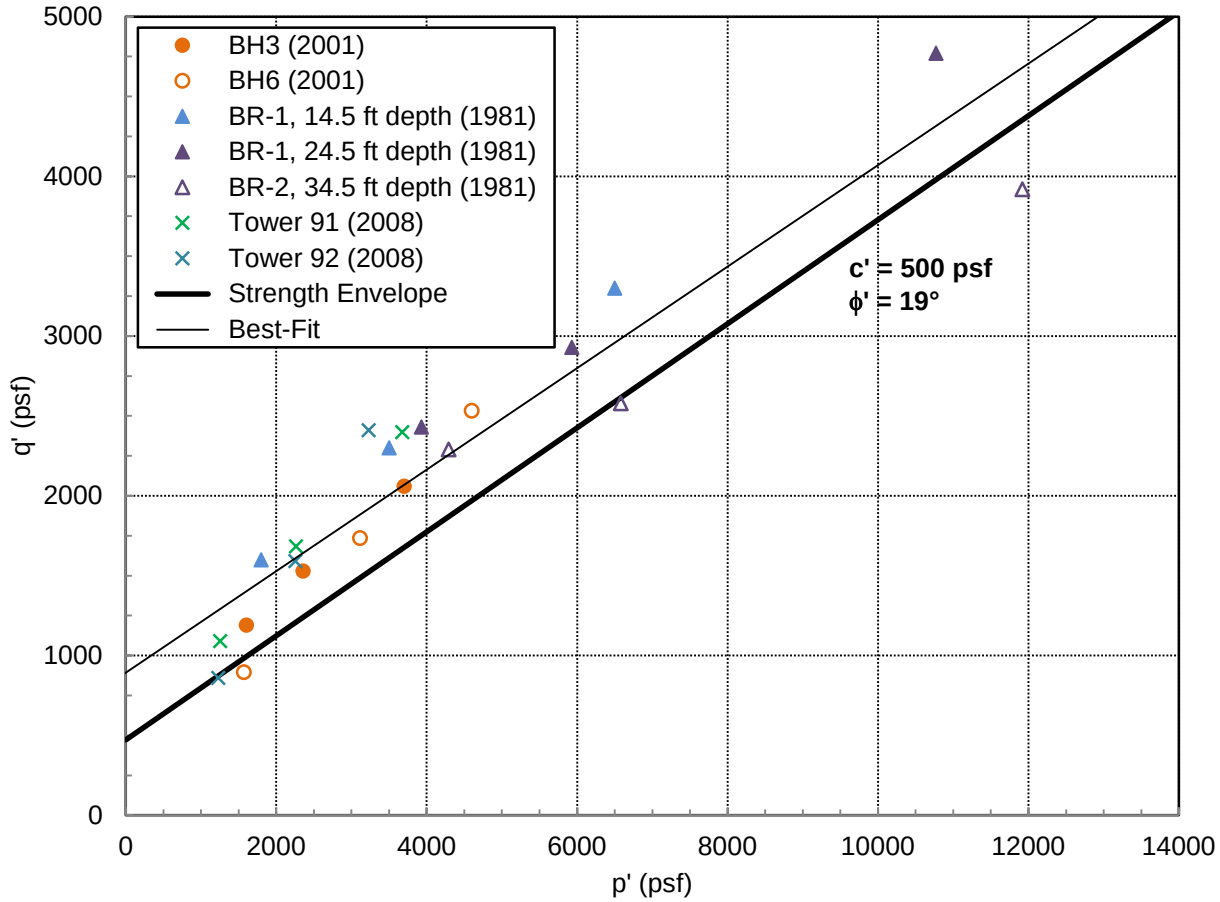

Figure 1: Strength Envelope for Existing Natural Soil Based on Triaxial Test Information

2.2 Clay Liner

Clay liner inputs are based on field experience and laboratory testing of materials at CCS. Dry unit weight and moisture content have been evaluated based on Shelby tube samples of other clay liners at CCS. Results yielded a dry unit weight ranging between 91.9 and 103.8 pcf (99.5 pcf average) and moisture content ranging between 18.6 % and 27. 7% (22.8 % average). Using a dry unit weight of 99.5 pcf and a moisture content of 23 %, a moist unit weight of 122 pcf was calculated and used for these stability analyses. Clay liner materials used at CCS come from existing natural clays onsite. Therefore, shear strength properties of the clay liner are the same as the existing natural soils: the effective cohesion is 500 psf and the effective friction angle is 19 degrees.

2.3 Sand Layer

Sand layer inputs were based on published values for SW and SP type material (NAVFAC 7.02).

Published maximum dry unit weight values range between 100 and 130 pcf (115 pcf average) with optimum moisture contents between 9 % and 21 % (15 % average). Assuming a construction specification of 95 % maximum dry density and optimum moisture, the dry unit weight chosen is 109 pcf with a moisture content of 15 %. This results in a moist unit weight value of approximately 125 pcf.

Published values for effective cohesion of SW and SP material suggest a value of 0 psf. Published values for effective friction angle of SW material suggest a value of 38 degrees. Published values for effective friction angle of SP material suggest a value of 37 degrees. For conservatism, the lower effective friction angle of the SP material was chosen for analyses.

2.4 Pit Run

Pit Run is described as a silty sand and inputs were based on published values for SM type material (NAVFAC 7.02).

Published maximum dry unit weight values range between 110 and 125 pcf (117.5 pcf average), with optimum moisture contents between 11 % and 16 % (13.5 % average). Assuming a construction specification of 95 % maximum dry density and optimum moisture, the dry unit weight chosen is 112 pcf with a moisture content of 13.5 %. This results in a moist unit weight value of approximately 125 pcf.

Strength parameters were based on the published values of 420 psf for effective cohesion and 34 degrees for effective friction angle (NAVFAC 7.02).

2.5 FGD Sludge Waste

FGD sludge waste input parameters are based on published data, field testing, design calculations, and lab work performed by Golder between 2001 and 2014.

Nine laboratory tests between 2002 and 2012 indicate an average specific gravity (G_s) of 2.7. Consolidation analyses indicate an average dry unit weight of about 45 pcf at the end of FGD sludge deposition, and an average dry unit weight of approximately 53 pcf after closure. Field sampling of saturated FGD sludge in test pits and from Shelby tubes indicate dry unit weights between 27 and 60 pcf. Assuming the FGD sludge is fully saturated during the active life of the facility, the saturated unit weight ranges between approximately 80 pcf at initial deposition and during intermediate deposition and 100 pcf at final deposition heights. Saturated unit weights are based on moisture contents as low as 65 % after closure to more than 100 % during deposition. Saturated unit weights used in analyses were based on consolidation analyses and generally vary between 89 pcf and 98 pcf depending on material depth. Saturated unit weight as a function

of depth is shown in the following table for the end of sludge deposition and after final cover has been placed:

Saturated Unit Weight vs. Height of Sludge

	Saturated Unit Weight	
Average Depth (ft)	**End of Sludge Deposition (pcf)**	**Final Cover Placed (pcf)**
>75	95	98
54-75	94	97
30-54	92	96
0-30	89	96

Consolidated-undrained triaxial lab testing was used to evaluate the strength of FGD sludge. Triaxial tests were performed on seventeen samples of FGD material between 2010 and 2014 at normal stresses between 1,000 and 10,000 psf on both remolded samples (2010 and 2012 samples) and intact Shelby tube samples (2014 samples). Golder conservatively developed the shear strength envelope based on triaxial tests to approximate the lower bound of shear strength test results (Figure 3). The strength envelope chosen for use in stability analyses is given in the following table:

Normal Stress (psf)	**Shear Strength (psf)**
0	270
5,500	1,500
10,000	2,500

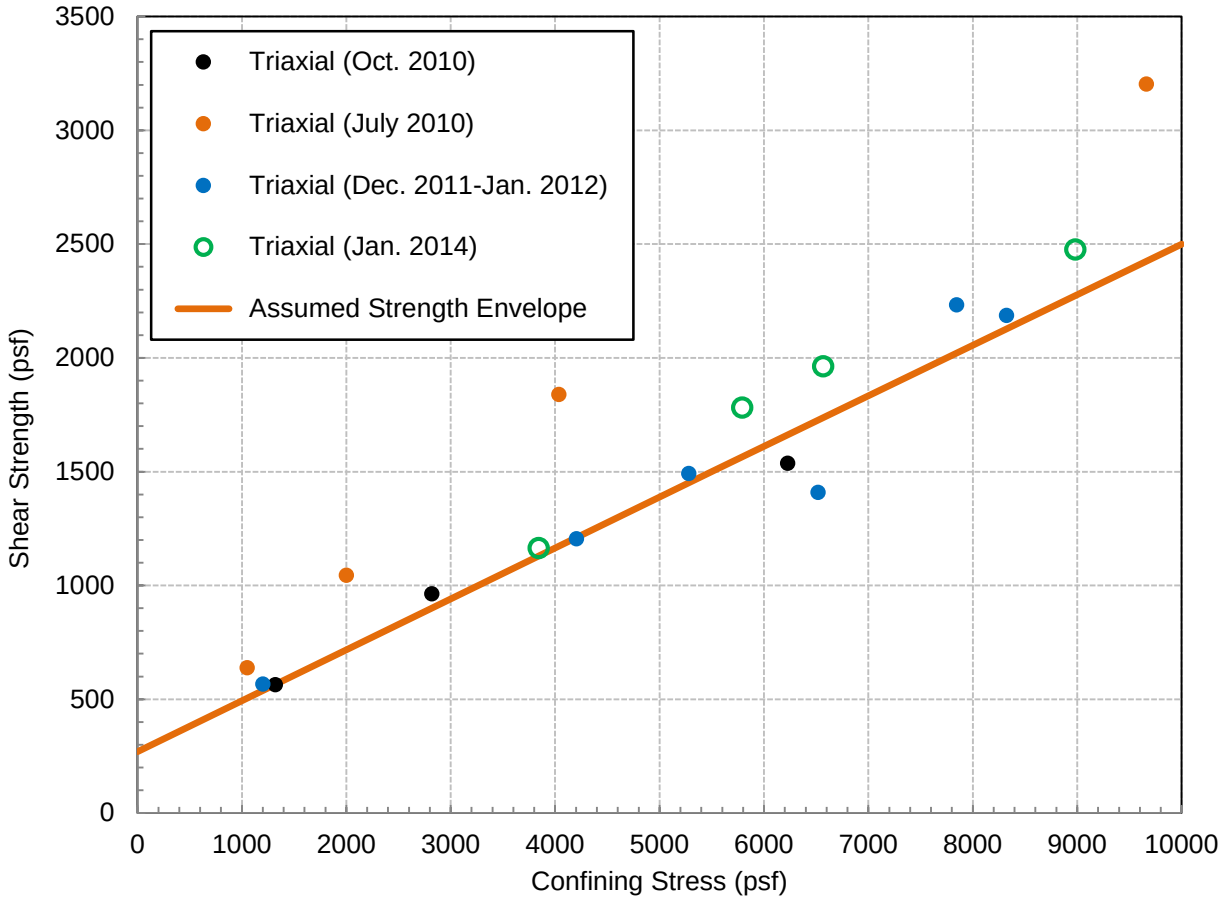

Figure 2: Shear Strength Tests Performed on FGD Sludge

2.6 Bottom Ash

Bottom Ash input parameters are based on lab and field work performed by Golder.

The dry unit weight for compacted bottom ash is based on 95 % standard Proctor densities from lab testing which gives a value of approximately 81 pcf. The dry unit weight of sluiced bottom ash is 60 pcf. An average value of 70 pcf was chosen for analysis based on a combination of compacted material and loosely placed material. The moisture content from field sampling of drained and saturated bottom ash ranged between 12 % and 61 %. For unsaturated conditions, a moisture content of 19 % was assumed. Using the lab measured specific gravity of bottom ash (2.60); the moisture content of bottom ash for saturated conditions was determined to be between 40 % and 65 % (average 53 %). Bottom ash was assigned an average moist unit weight of 83 pcf and an average saturated unit weight of 107 pcf.

Lab direct shear strength testing of bottom ash indicated a residual effective cohesion of 463 psf and a residual friction angle of 40.3 degrees. Visual observations of the bottom ash material indicates little cohesion, therefore the effective cohesion was chosen as 50 psf and an effective friction angle of 40 degrees was chosen for analysis.

2.7 Fly Ash

Fly Ash input parameters are based on triaxial tests performed by Golder for a 75 % solids paste mix and unconfined compression tests performed on fly ash samples prepared using standard Proctor compaction techniques.

Dry unit weights from triaxial tests ranged between 87.8 pcf and 94.5 pcf with an average value of 91.9 pcf; a value of 92 pcf was chosen. Moisture contents from the same testing ranged between 6.3 % and 27.7 % with an average value of 16 %; a value of 16% was chosen. These values result in a moist unit weight of 107 pcf.

Triaxial tests were performed on the fly ash to evaluate the shear strength. Samples were allowed to “cure” for between 28 and 56 days prior to testing to evaluate long-term behavior. The results of the test provided an average cohesion of 1610 psf with a friction angle of 32 degrees. These properties were used in the stability analyses.

2.8 Geosynthetic Interfaces

Geomembrane Interface inputs are based on lab work performed by Golder and published values (GRI 2005). The interfaces of interest are:

- Smooth HDPE against clay liner.
- Smooth HDPE against sand or bottom ash.

Geosynthetic interface shear strengths are based on interface shear test results and consider both peak and residual shear strengths. Two large-scale direct shear interface friction tests were performed between a 40-mil smooth high density polyethylene (HDPE) liner and site specific clays representative of those used in liner construction. The HDPE liner used in testing was excavated from site facilities and is similar to what was used during construction of Ash Pond 91. Results of the two tests indicate a friction angle of about 7.5 degrees and a residual adhesion intercept of approximately 200 psf for smooth HDPE against clay liner (Figure 2).

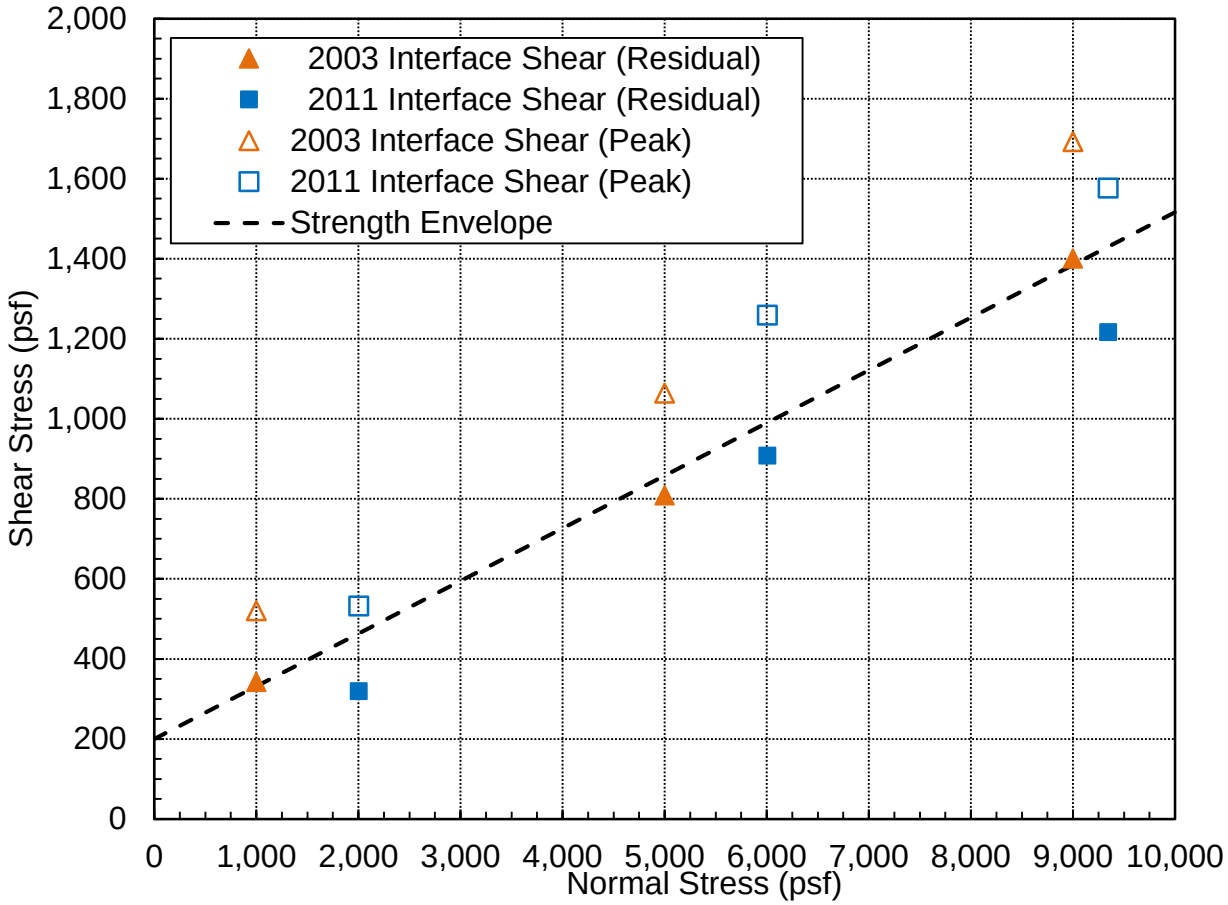

Figure 3: Interface Shear Tests for Smooth HDPE against Site-Specific Clay

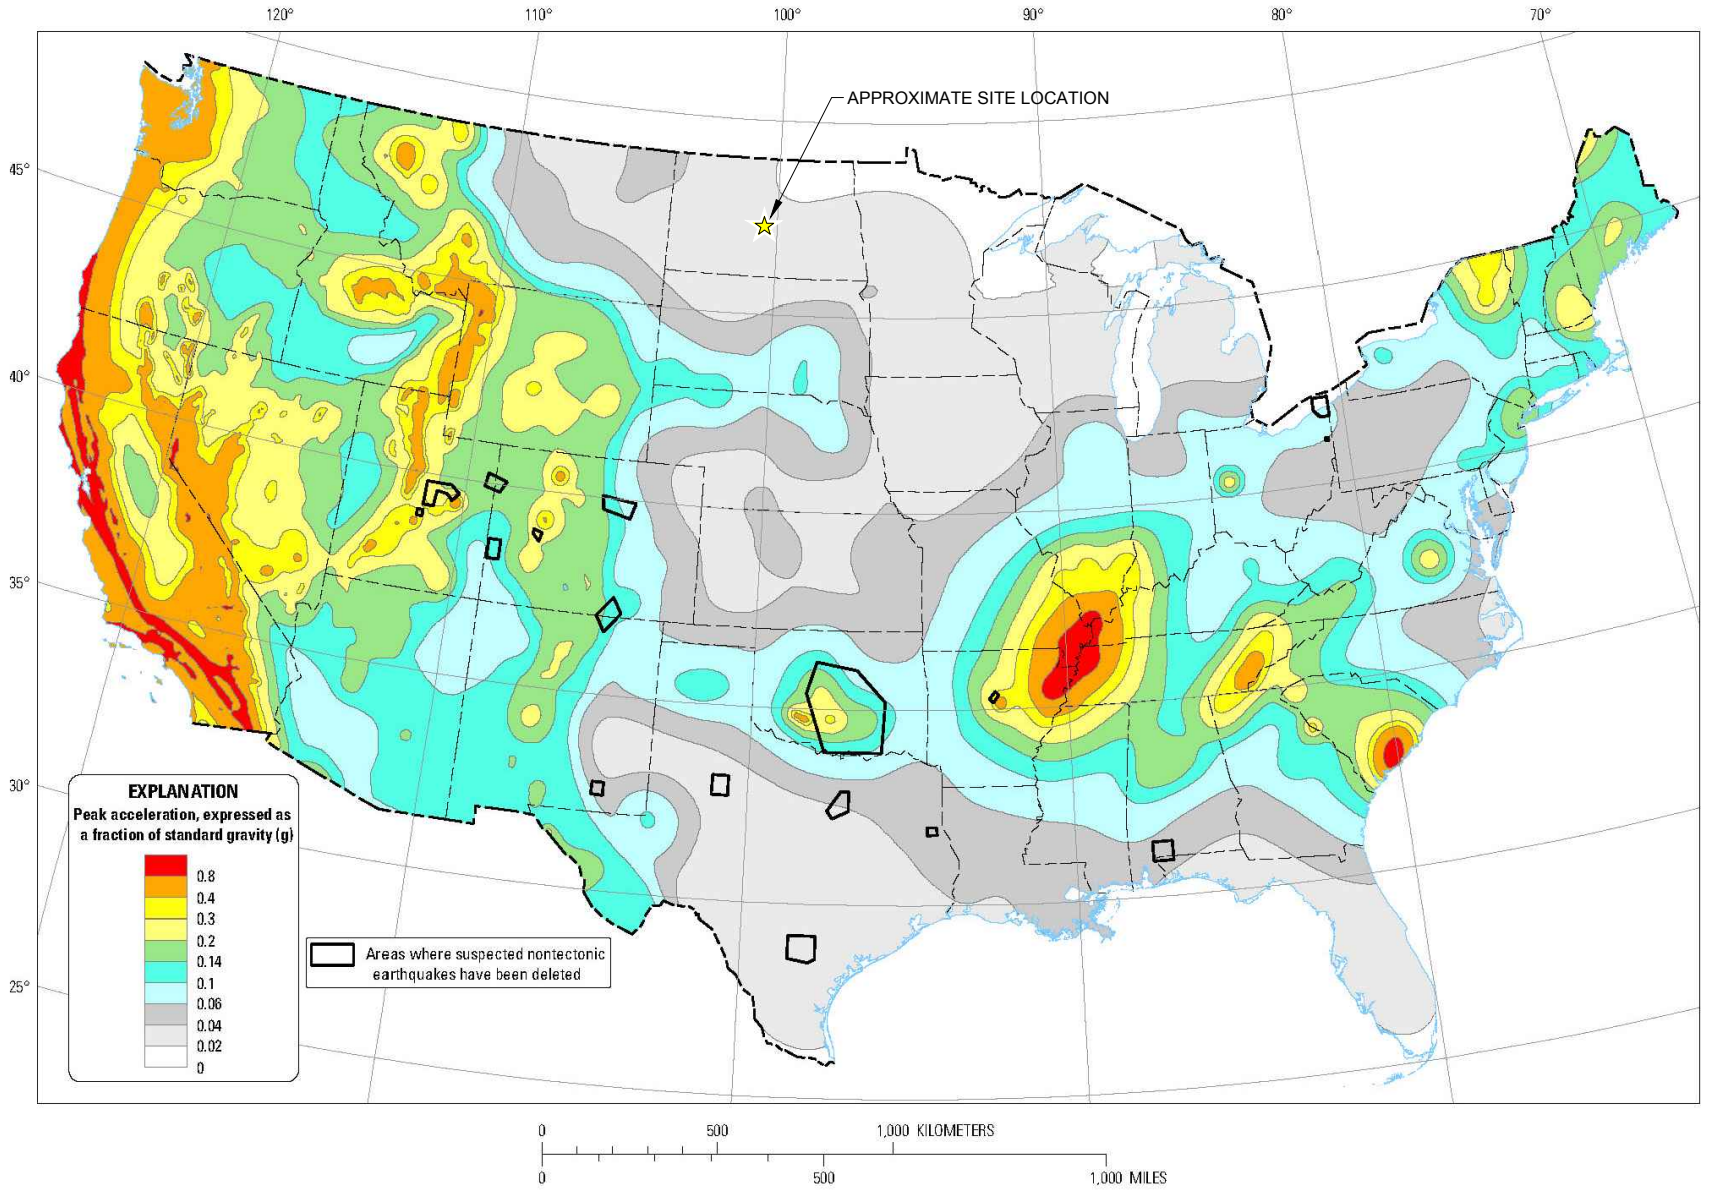

Golder lab experience for smooth HDPE against sand indicates a residual friction angle between 13.4 and 20 degrees (average of 16.7 degrees) and a residual adhesion intercept between 0 and 72 psf (average of 36 psf). The Geosynthetic Research Institute (GRI 2005) published a residual friction angle of 17 degrees and a residual adhesion intercept of 0 psf for smooth HDPE against granular soil based on 128 tests. Based on Golder lab experience and GRI (2005), a friction angle of 17 degrees with no adhesion intercept was chosen for use in engineering analysis.

1.0 INTRODUCTION

Golder Associates Inc. (Golder) has prepared this revision to the Coal Combustion Residual (CCR) Groundwater Monitoring System Certification Report on behalf of Great River Energy (GRE) to certify that the groundwater monitoring system for the CCR facilities at Coal Creek Station regulated by the United States Environmental Protection Agency's (EPA) CCR rule meets the requirements of 40 CFR 257.91.

2.0 SITE BACKGROUND

GRE's Coal Creek Station (CCS) is a coal-fired electric generation facility located in McLean County, North Dakota, approximately 10 miles northwest of Washburn, ND. CCRs are managed in composite-lined surface water impoundment cells and dry waste facilities regulated and permitted by the North Dakota Department of Health (NDDH) in accordance with North Dakota Administrative Code (NDAC) Article 33-10, Solid Waste Management and Land Protection.

Coal Creek Station has four CCR facilities that are within the purview of the EPA CCR rule (see Figure 1):

- Drains Pond System CCR Surface Impoundment (Drains Pond System) is located in the south-central portion of the plant site, northeast of the plant buildings.
- Upstream Raise 91 CCR Surface Impoundment (Upstream Raise 91) is located in the south-central portion of the plant site, east of the plant buildings.
- Upstream Raise 92 CCR Surface Impoundment (Upstream Raise 92) is located in the southeast portion of the plant site, between Upstream Raise 91 and Southeast Section 16.
- Southeast Section 16 CCR Landfill (Southeast 16) is located in the southeast portion of the plant site, east of Upstream Raise 92.

2.1 Site Setting

The area surrounding CCS is primarily characterized by the presence of mixed glacial deposits. The following section detail the regional and site geology and hydrogeology.

2.1.1 Regional and Site Geology

CCS and McLean County are situated at the eastern-most extent of the Williston Basin, a structural and sedimentary basin (USGS 1999). The region is characterized by the presence of glacial drift, reaching thicknesses of several hundred feet, and overlying the Sentinel Butte Member, the source of commercially mined coal in the direct vicinity of CCS (Falkirk 1979). The Sentinel Butte Member is the highest strata of the Paleocene Fort Union Formation, overlying the Tongue River, Ludlow, and Cannonball Members (USGS 1999). The Sentinel Butte Member is marked by drab-gray units, separating it from the lower Tongue River Member.

The site geology of CCS includes unconsolidated surficial deposits of the Coleharbor formation consisting of stratified and unstratified glacial drift. The near-surface materials are silty clay and sandy clay till with interbedded sand lenses (CP/UPA 1989).

2.1.2 Site Hydrogeology

Regional groundwater flow of the uppermost water-bearing unit in the vicinity of CCS is a subtle expression of the surface topography, which is influenced by the configuration of the eroded bedrock. Based on the October 2018

groundwater elevations (shown in Figure 1), the shallow groundwater at the CCR facilities generally follows surface topography, flowing the east and north towards Lower Samuelson Slough and Sayler Slough.

The groundwater gradient across the CCR sites was estimated from the October 2018 groundwater levels, and ranges from 0.002 to 0.03 feet per feet (ft/ft). Slug testing was performed at several site monitoring wells in 2007 and resulting in estimated hydraulic conductivity values between 8×10^{-3} centimeters per second (cm/sec; 22.7 feet/day) and 1×10^{-4} cm/sec (0.28 feet/day).

2.1.3 Geologic Cross Sections

Geologic cross sections were compiled based on boring information from current CCR monitoring wells and historic site monitoring wells and boreholes (Appendix A).

As shown in the cross sections and described previously, variability within the area of the site results in a range of geologic materials within the near-surface geologic units. Discontinuous seams of coal are located throughout the site, in addition to gravel, sand, silt, and clay.

2.2 Release Conceptual Model

A hypothetical subsurface release from any of the four facilities located at CCS, would be transported downgradient of each facility, as demonstrated by the groundwater information presented in Figure 1. The downgradient wells discussed in Section 3.2 are positioned along the downgradient edges of each CCR facility to detect a release.

3.0 GROUNDWATER MONITORING SYSTEM

The CCR groundwater monitoring system at CCS consists of a total of 23 monitoring locations (eight upgradient and fifteen downgradient wells). The monitoring locations are shown on Figure 1 and listed on Table 1.

3.1 Information Reviewed

Golder reviewed information from the operating record documenting the design, installation, and development of the monitoring wells and/or describing hydrogeologic conditions at the site to help assess the adequacy of the monitoring network. The information reviewed included:

Cooperative Power and United Power Associations. 1989. Application to Renew Permit SU-033 – Coal Creek Station, McLean County, North Dakota. Submitted to the North Dakota State Department of Health. February 1989.

Falkirk Mining Company. 1979. Land Use Analysis/Technical Examination/Environmental Assessment Record – Falkirk Coal Lease Application M-31053 (ND). Submitted to the United States Department of the Interior, July 1979.

Foth & Van Dyke and Associates, Inc. 1988. Hydrogeological Analysis – Coal Creek Station, McLean County, North Dakota. Prepared for Cooperative Power, Eden Prairie, Minnesota, and United Power Association, Elk River, Minnesota. December 1988.

Foth & Van Dyke and Associates, Inc. 1989. Drilling Data – Summer 1989 – Coal Creek Station, McLean County, North Dakota. Prepared for Cooperative Power, Eden Prairie, Minnesota, and United Power Association, Elk River, Minnesota. December 1989.

United States Geological Survey. 1999. Fort Union Coal in the Williston Basin, North Dakota: A Synthesis. Chapter WS in 1999 Resource Assessment of Selected Tertiary Coal Beds and Zones in the Northern Rocky Mountains and Great Plains Region, U.S. Geological Survey Professional Paper 1625-A.

3.2 Number, Locations, and Depths of Monitoring Wells

40 CFR 257.91 includes the following requirements for the number, locations, and depths of monitoring wells:

- The owner or operator of a CCR unit must install a groundwater monitoring system that consists of a sufficient number of wells, installed at appropriate locations and depths, to yield groundwater samples from the upper most aquifer that:
  - Accurately represent the quality of background groundwater.
  - Accurately represent the quality of groundwater passing the waste boundary of the CCR unit.
- The number, spacing, and depths of monitoring wells must be based on site-specific technical information that must include thorough characterization of the uppermost aquifer and overlying materials.
- The groundwater monitoring system must include the minimum number of monitoring wells necessary to meet the performance standards based on the site-specific information. The groundwater monitoring system must contain a minimum of one upgradient monitoring well and three downgradient monitoring wells per unit.

Each CCR unit has a monitoring network consisting of a least one upgradient and three downgradient monitoring wells as specified within the rule, as discussed below.

- The Drains Pond System has two upgradient and four downgradient monitoring wells.
- Upstream Raise 91 has two upgradient and three downgradient monitoring wells.
- Upstream Raise 92 has two upgradient and three downgradient monitoring wells.
- Southeast 16 has two upgradient and five downgradient monitoring wells.

Monitoring well construction details are provided on Table 1 and Appendix B. The monitoring wells assigned to each facility are as follows:

Table 2: CCR Units Monitoring Wells

Drains Pond System	Upgradient	MW-DP3
		MW-DP5
	Downgradient	MW-DP1
		MW-DP2
		MW-DP2B
		MW-DP4
Upstream Raise 91	Upgradient	MW-91-2
		MW-75
	Downgradient	MW-49
		MW-51
		MW-91-1
Upstream Raise 92	Upgradient	MW-16-6
		MW-16-7
	Downgradient	MW-10
		MW-16-0
		MW-16-1
Southeast 16	Upgradient	MW-42
		MW-72
	Downgradient	MW-16-2
		MW-16-3
		MW-16-4
		MW-16-5
		MW-15

The monitoring wells are installed and screened at appropriate locations and depths to obtain groundwater from the uppermost water bearing zone. The number and spacing of the downgradient monitoring wells were selected based on the hydrogeologic conditions at the site and the areal extent of the CCR units, such that impacts to groundwater quality in the uppermost water bearing unit can be detected along potential flow pathways if they were to occur.

General solid waste industry practice includes placing monitoring wells downgradient of the waste disposal area within the property boundary and within 150 meters of the waste boundary. The distance from the waste boundary to the monitoring wells should be based on the presumed flow directions, groundwater seepage velocity, access/location limitations, and distance to provide sufficient space between the waste boundary and the monitoring network to allow for hydrodynamic dispersion, which increases the probability of detection of a potential release. The downgradient monitoring wells at the CCR facilities at CCS were primarily installed as part of previous state monitoring requirements and are located at appropriate distances as close as practical to the waste boundary. Further, the downgradient wells for Section 16 have been placed based on the historic permitted waste boundary for the facility.

3.2.1 Drains Pond System

The Drains Pond System has four downgradient monitoring wells monitoring downgradient water at three locations. MW-DP2B was installed as a companion well to MW-DP2, which has on occasion not had enough groundwater present in the well for water quality sampling. The three downgradient monitoring locations are based on observations that show groundwater flows to the northeast corner of the facility. A hypothetical release from this facility is anticipated to impact a relatively small areal extent, based on the footprint of the system and groundwater flow information. Therefore, based on site geometry and the groundwater flow direction, the four downgradient wells shown on Figure 1 were deemed adequate to monitor the groundwater flow regime of the Drains Pond System.

3.2.2 Upstream Raise 91

Upstream Raise 91 has three downgradient monitoring wells based on the length of the northern boundary of the facility and observations that show groundwater flows from southwest to northeast across the facility towards Lower Samuelson Slough. Based on site geometry and the groundwater flow direction, the spacing of the downgradient wells across the northern boundary as shown on Figure 1 were deemed adequate to monitor the groundwater flow regime of Upstream Raise 91.

3.2.3 Upstream Raise 92

Upstream Raise 92 has three downgradient monitoring wells based on observations that show groundwater flows from southwest to northeast across the facility. Based on the footprint of the system, the areal extent of the northern boundary of the facility, and the groundwater flow information, the three downgradient wells shown on Figure 1 were deemed adequate to monitor the groundwater flow regime of Upstream Raise 92.

3.2.4 Southeast 16

Southeast 16 has five downgradient wells along the northern and eastern boundaries of the facility, based on observations that show groundwater flows generally to the northeast of the facility. Based on the site geometry and the groundwater flow direction within the facility, the five downgradient wells shown on Figure 1 were deemed adequate to monitor the groundwater flow regime of Southeast 16.

3.3 Monitoring Well Casing

40 CFR 257.91(e) includes the following requirements for monitoring well construction:

- “Monitoring wells must be cased in a manner that maintains the integrity of the well borehole.
- The casing must be screened or perforated and packed with gravel or sand to enable collection of groundwater samples.

- The annular space above the sampling depth must be sealed to prevent contamination of samples and the groundwater."

The monitoring wells at CCS have polyvinyl chloride (PVC) casings to maintain the integrity of the monitoring well boreholes. The casings are screened within the uppermost water bearing unit and packed with sand to enable collection of groundwater samples within the unit. The annular space above the screened interval in each monitoring well is sealed with a bentonite seal and cement-bentonite grout seal.

4.0 REVISION HISTORY

A history of revisions to this document:

Revision 0 – Published October 12, 2017.

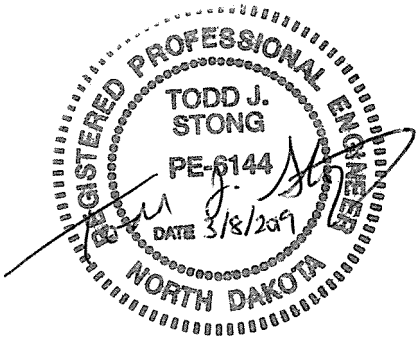
Revision 1 – Revised to reflect: Published March 8, 2019

1) Addition of new wells at the site (MW-DP2B, MW-16-0, MW-91-1, MW-91-2);

2) New CCR unit naming convention (Upstream Raise to Upstream Raise 92 and Ash Pond 91 to Upstream Raise 91); and

3) Division of Upstream Raise 91 and Upstream Raise 92 into separately monitored CCR units.

5.0 CLOSING AND CERTIFICATION



Based upon the review described in this report, the undersigned certifies that the groundwater monitoring system for the Drains Pond System, Upstream Raise 91, Upstream Raise 92, and Southeast 16 at Coal Creek Station has been designed and constructed to meet the requirements of 40 CFR 257.91.

Notes:
TOC: top of casing
ft amsl: feet above mean sea level
ft bgs: feet below ground surface
1. For MW-DP5, the ground surface elevation is taken from the original bore log, but is inconsistent with the available survey for the top of casing.
2. For MW-DP1 only the top of casing elevation was provided. The PVC riser was assumed to be 2.5 ft above ground surface.
3. For MW-DP2B only the top of casing elevation was provided. The PVC riser was assumed to be 3.0 ft above ground surface.
Well construction measurements are from the original bore log, well data sheet, or well construction form.
For some wells, elevations have been updated with more recent survey information than the original driller's logs.

Stratification lines are approximate. In-situ, the transition may be gradual.

Hammer Type: Automatic

Advancement Method:
3¼" ID HSA 0-33'

Abandonment Method:
Boring converted to monitoring well installation.

See Exhibit A-3 for description of field procedures.

See Appendix B for explanation of symbols and abbreviations.

Notes:

Elevation, Northing and Easting provided by client.
Latitude and Longitude measured by Terracon.
Sloping concrete collar at the surface.
Three steel bollards installed around well.
Well developed July 17. Pumped water until clear (0.5 hrs).

WATER LEVEL OBSERVATIONS

- *While drilling*
- *At completion of drilling*
- *After 68 hrs*

MONITORING WELL REPORT

State law requires that this report be filed with the State Board of Water Well Contractors within 30 days after completion or abandonment of the well.

1. WELL OWNER

Name Great River Energy

Address 2875 3rd St SW

Underwood, ND 58576-9659

2. WELL LOCATION **(Well MW-16-7)**

Address (if in city) (see attached drawing)

County McLean

SE ¼ SE¼ SW¼ Sec. 16 Twp. 145 N. Rge. 82 W

Lat: 47.3722 Long.: -101.13292

Ground Elevation: 1907

3. METHOD DRILLED

■ Auger Other ____

4. WELL CONSTRUCTION

Diameter of Hole 6.25 inches Depth 33 feet

Riser: ■ PVC □ Other

■ Threaded □ Solvent □ Other

Riser rating SDR _____ Schedule 40

Diameter 2.0 inches

From +2.75 ft. to 22 ft.

Was a well screen installed? ■ Yes □ No

Material Schedule 40 PVC Diameter 2.0 inches

Slot Size #10 set from 22 feet to 32 feet

Sand packed from 20 feet to 32 feet

Depth grouted from 1 foot to 20 feet

Grouting Material

Bentonite x Other _____

If other explain:

One foot thick concrete collar at the surface.

Sluff: 32 feet to 33 feet

Three steel bollards installed around well.

Well head completion:

24" above grade _____ Other x

If other, specify 4" x 4" x 5' square steel protective cover

Was protective casing installed? ■ Yes □ No

Was well disinfected upon completion? □ Yes ■ No

5. WATER LEVEL

Static water level 24 feet below surface

If flowing: closed in pressure _____ psi or ft. above land surface

6. WELL LOG Depth (Ft.)

Formation	From	To
SANDY LEAN CLAY	0	13
CLAYEY SAND	13	20.5
FAT CLAY	20.5	24
CLAYEY SAND	24	29
SANDY LEAN CLAY	29	33

(Use separate sheet if necessary)

7. WAS THE HOLE PLUGGED OR ABANDONED?

□ Yes ■ No

If so, how? _____

8. REMARKS

Water level monitoring only

9. DATE COMPLETED 7-17-15

10. CONTRACTOR CERTIFICATION

This well was drilled under my jurisdiction and this report is true to the best of my knowledge.

Terracon 444

NDB90-045 ANNUAL HYDROGEOLOGICAL ANALYSIS REPORT
Coal Creek Station
McLean County, North Dakota

A. INTRODUCTION

This Annual Hydrogeological Analysis Report is submitted pursuant to the permit requirements set forth by the State of North Dakota Department of Health and Consolidated Laboratories (SDH) for the Coal Creek Station, McLean County, North Dakota.

This report includes data summary tables and graphs of selected available data as well as a narrative discussion of the water quality in the areas of the evaporation ponds and disposal ponds.

In addition, the interpretation of the 1989 Electromagnetic Survey (EM) as it correlates with the chemical samples is included. This is a requirement of the SDH as a provision for the site permit.

A site location map is shown in Figure 1; Figure 2 is a site map illustrating the location of monitoring points. Plate 1 displays an enlarged copy of the site map.

B. BACKGROUND

Background information was compiled out of the reports listed in the Reference section (F.).

The surficial geology consists of a sequence of glacial tills over sedimentary bedrock units. The till units range up to 30 feet thick. Beneath the till is an eroded surface of poorly consolidated sediments. In the south/southwest portion of the site, a shale and lignite unit is encountered as the first bedrock, which, in turn, overlies a sandstone unit.

Water level data for the site ~~is~~ are available dating back to the fourth quarter of 1979. A majority of the monitoring system was installed prior to 1986, when the monitoring system consisted of 39 wells. In 1986, eight additional groundwater monitoring wells were installed. In the spring of 1988 an

BRAUN™

obvious spatial correlation exists. This further supports the conclusion that EM values and contaminant levels are not correlated.

33	88.2	1900.00	612.50
18	90.1	5000.00	3077.50
49	90.6	4400.00	2292.50
85	94.1	6600.00	2995.00
88	115.2	20000.00	14250.00

Surface water quality trends are shown on Figures 22-25. Upper and Lower Gradin Slough have been dry since the spring of 1989, but the historical data is presented on the graphs.

The monitoring system for the ash ponds went through a revision. Data previously presented by the monitoring point labeled "South Ash Pond" is now monitored by sites 126 and 127, East South Ash Pond and West South Ash Pond. Due to the change in monitoring points for the South Ash Pond, no new data is available for the 1989 monitoring period to compare with previous levels. The values are significantly lower than previously measured, but it is not know whether this is a reoccurring trend.

Sulfate and specific conductance levels have increased in Samuelson Slough over the 1989 monitoring period. These levels are significantly higher than previous values. Saylor Slough values remained at levels relative to previous measurements. Data was not available for Gradin Slough due to drought conditions.

BRAUN™

	SPECIFIC CONDUCTANCE umhos/cm			SULFATE, mg/l			BORON, mg/l		
91	-	1370.00	-	-	275.00	-	-	0.64	-
92				-	-				
93	-	11400.00	-	-	6340.00	-	-	0.91	-
94	-	4000.00	-	-	1300.00	-	-	0.56	-

A comparison of the specific conductance versus sulfate was performed to determine if previous trends still exist. The data was sorted based on increasing sulfate concentrations. The results are shown on Figures 18 and 19. As can be seen, the linear relationship previously found for the compounds still exists, except for the highest concentration data points. Figure 19 excludes the highest data points for each monitoring session in the data set.

The correlation between boron levels and the sulfate levels, as shown on Figure 20, also indicates a linear relationship, but with a larger relative change in the boron concentrations as compared to the sulfate values.

The geophysical work presented in the November 15, 1989 report relates to the groundwater data presented for analysis. Table 6 lists the EM conductivity values and their corresponding well locations, sorted by increasing EM values.

The comparison of the EM data to the chemical results has previously been reported by Foth and Van Dyke to exhibit a linear relationship between EM and specific conductance and sulfate levels, based on a limited number of data points. This conclusion is not supported by the new data. As can be seen on Figure 21A, there appears to be no correlation between increasing EM values and the groundwater contaminant levels. In order to further evaluate whether this potential relationship exists, wells with EM values above 60 mmhos/meter (roughly the highest 50% of the readings) were plotted relative to potential contaminant source areas (Figure 21B). As can be seen, these wells are located both upgradient and downgradient of the evaporation ponds and disposal areas. Hence, no

additional 21 groundwater monitoring wells were installed. A total of 68 groundwater monitoring wells have now been constructed. This number does not include the observation wells and piezometers.

Previous data indicated the apparent groundwater flow directions are influenced by surface topography, with local influences from the surface impoundments. The generalized surface water flow path through the watershed passes consecutively through Weller Slough, Samuelson Slough, Sayler Slough, Gradin Slough and into the Coal Lake Coulee and/or Buffalo Creek drainage systems.

Previous vertical gradients measured within the groundwater flow system indicated that mounding was occurring beneath the surface impoundments. The hydrographs from the monitoring points in both deep and shallow wells have shown similar response to stresses on the flow system. Thus, it was concluded that deep and shallow groundwater act as a connected hydrological system.

Increases in specific conductance levels and sulfate concentrations have been observed over time in the groundwater. ~~This~~ esp data ~~was~~ were correlated with the geophysical data (electromagnetic survey) as presented in the March 1989 report prepared by Foth and Van Dyke. The comparison of the data as made by Foth and Van Dyke indicated that a linear relationship existed between the EM data and the specific conductivity values. Additionally, the specific conductivity values and the sulfate values showed a linear correlation.

C. GROUNDWATER ELEVATION INFORMATION

Table 1 below presents groundwater elevations available for the 1989 reporting period. Historical groundwater elevation data ~~is~~ are included in Appendix 1.

Groundwater contour maps are presented on Figures 3A and 3B. The flow patterns indicate that the surface topography and interactions between groundwater discharge and surface water are the major influences on the flow domain. Based on these figures, it appears groundwater flow is towards the sloughs where it discharges into the slough complex. Some of the groundwater is lost to evapotranspiration. Across the site flow moves to the east-southeast in the direction of Sayler Slough.

The hydrographs for selected wells (6, 9, 10, 11, 13, 14 and 15) are shown on Figures 4-10. A combined hydrograph presentation is shown on Figure 11. These wells were chosen because they had a substantial amount of historical data to which to evaluate recent water levels and they were also

additional 21 groundwater monitoring wells were installed. A total of 68 groundwater monitoring wells have now been constructed. This number does not include the observation wells and piezometers.

Previous data indicated the apparent groundwater flow directions are influenced by surface topography, with local influences from the surface impoundments. The generalized surface water flow path through the watershed passes consecutively through Weller Slough, Samuelson Slough, Sayler Slough, Gradin Slough and into the Coal Lake Coulee and/or Buffalo Creek drainage systems.

Previous vertical gradients measured within the groundwater flow system indicated that mounding was occurring beneath the surface impoundments. The hydrographs from the monitoring points in both deep and shallow wells have shown similar response to stresses on the flow system. Thus, it was concluded that deep and shallow groundwater act as a connected hydrological system.

Increases in specific conductance levels and sulfate concentrations have been observed over time in the groundwater. ~~This~~ ex data ~~was~~ were correlated with the geophysical data (electromagnetic survey) as presented in the March 1989 report prepared by Foth and Van Dyke. The comparison of the data as made by Foth and Van Dyke indicated that a linear relationship existed between the EM data and the specific conductivity values. Additionally, the specific conductivity values and the sulfate values showed a linear correlation.

Groundwater contour maps are presented on Figures 3A and 3B. The flow patterns indicate that the surface topography and interactions between groundwater discharge and surface water are the major influences on the flow domain. Based on these figures, it appears groundwater flow is towards the sloughs where it discharges into the slough complex. Some of the groundwater is lost to evapotranspiration. Across the site flow moves to the east-southeast in the direction of Sayler Slough.

The hydrographs for selected wells (6, 9, 10, 11, 13, 14 and 15) are shown on Figures 4-10. A combined hydrograph presentation is shown on Figure 11. These wells were chosen because they had a substantial amount of historical data to which to evaluate recent water levels and they were also

specified in the permit application. Compared to previous years, water levels are appreciably lower based on trends displayed in Figure 11, with the exception of MW-13.

Vertical gradients are seen in the areas of the sloughs, ponds, disposal areas, and basins. Table 2 below lists the relative changes in water levels per unit vertical distance at the nested wells (the vertical gradients). These vertical gradients are consistent with previous observations. A negative sign in the table indicates a downward gradient. Upward vertical gradients are more common across the site which is to be expected in a groundwater discharge area such as the one these sloughs comprise.

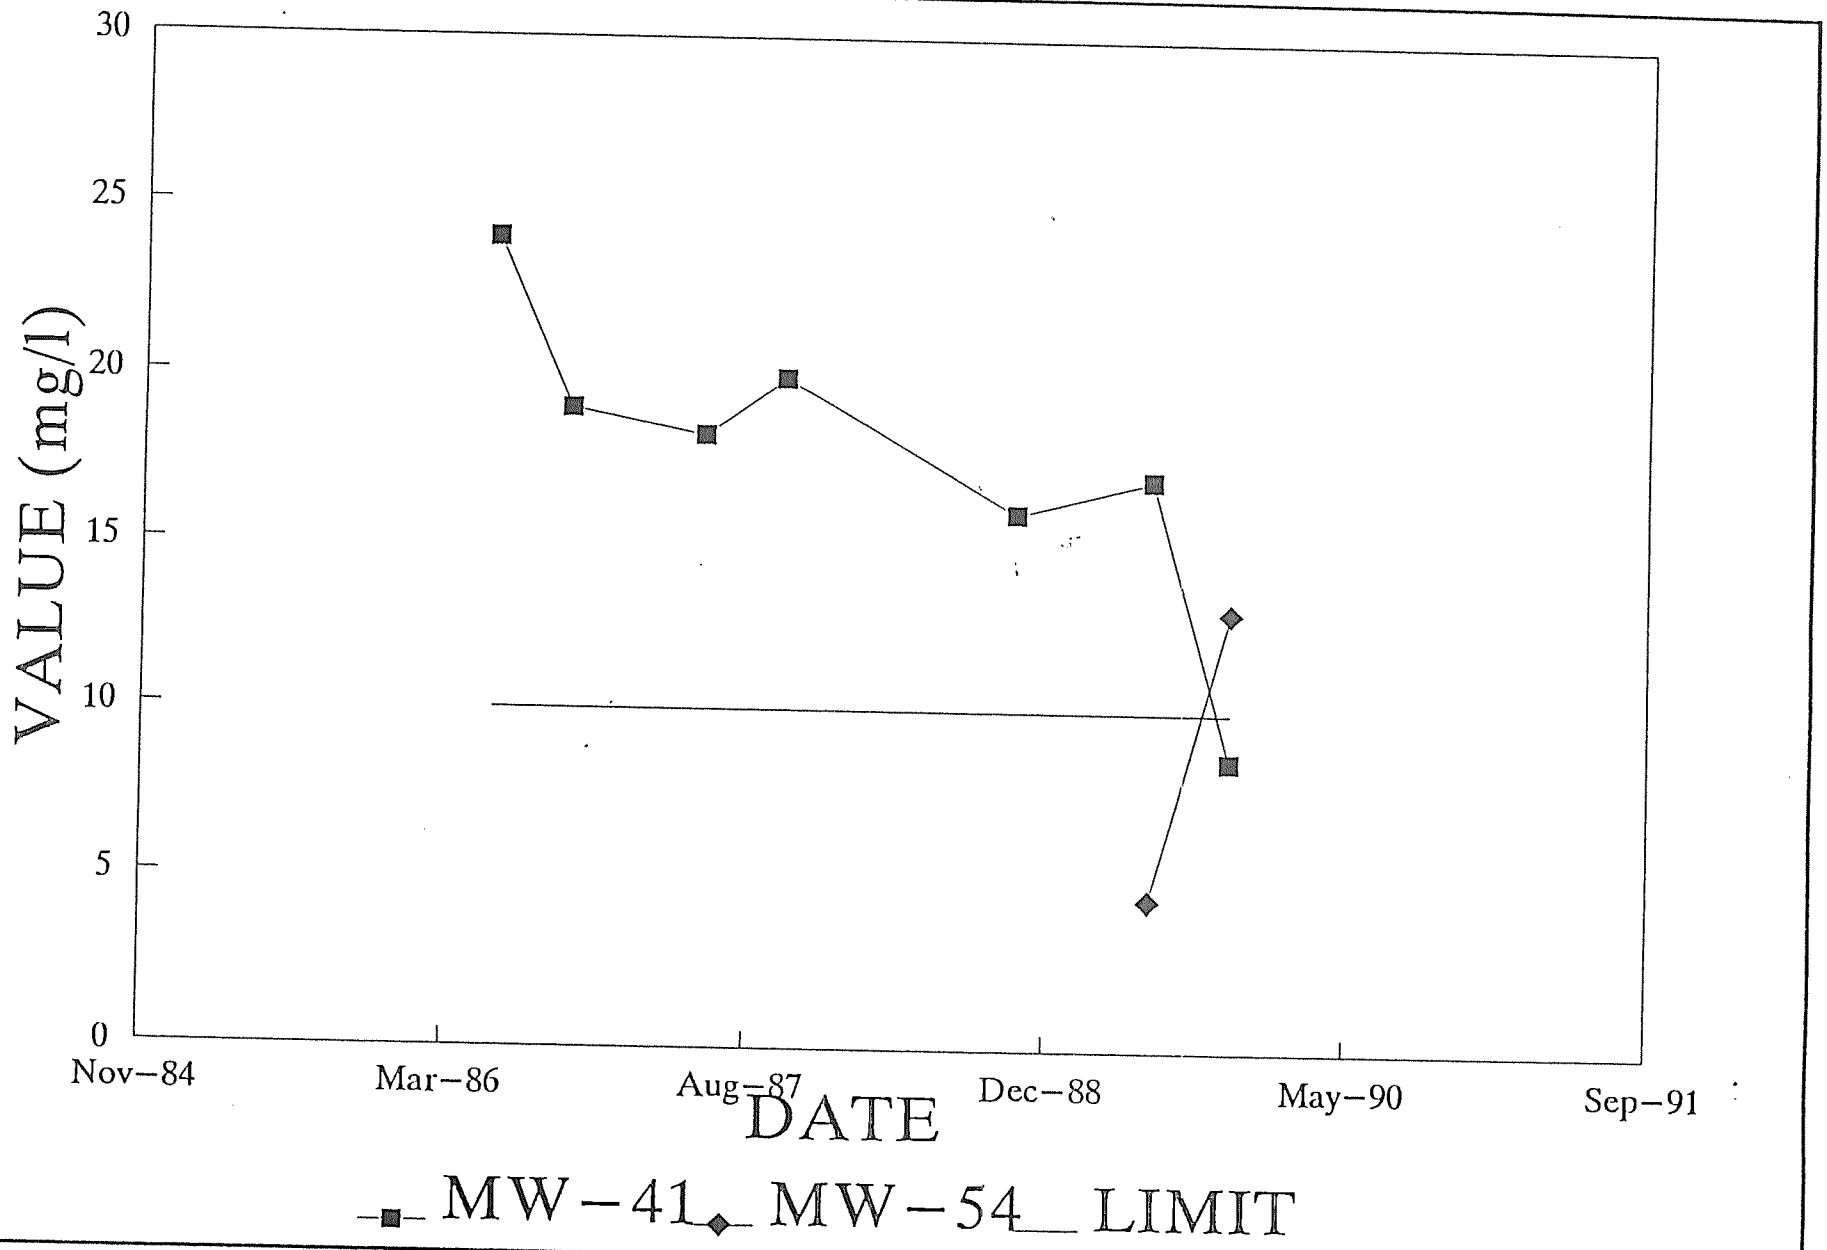
D. ANALYTICAL RESULTS



Groundwater was sampled in the second and fourth quarters of 1989. The table below lists the parameters for the sampling sessions. Complete groundwater sample laboratory results are presented in Appendix 2 along with historical data.

TABLE 3
SAMPLING PARAMETERS

TABLE 4
EXCEEDANCE OF FEDERAL CRITERIA (MCLs)

Well	Compound	MCL	Units	Value	Date
MW-41	Nitrate	10	mg/l	17.00	06/89
MW-54	Nitrate	10	mg/l	13.00	10/89
MW-32	Selenium	10	ug/l	44.50	06/89
MW-77	Selenium	10	ug/l	114.00	10/89
MW-79	Selenium	10	ug/l	525.00	10/89
MW-85	Selenium	10	ug/l	12.00	10/89
MW-14	Fluoride	4	mg/l	8.50	06/89
MW-14	Fluoride	4	mg/l	7.90	10/89

Because nitrate and selenium levels have not shown an increase over time, levels above MCLs may be natural. Fluoride, on the other hand, has shown increases in some wells, although clearly not in most wells.

Although various parameters have been detected at the monitoring points, the discussion below focuses on the compounds that have been listed in previous reports as general indicator parameters for water quality (specific conductivity, sulfate and boron). Table 5 lists the data for specific conductivity, sulfate and boron for the 1989 sampling sessions. Graphs of the data are shown on Figures 15-17.

Figures 15, 16 and 17 consistently indicate increased concentrations over time in wells 10, 14 and 15. These are shallow wells in the immediate vicinity of the section 16 disposal area. Wells 6, 9, 11 and 13 are either deep wells, or shallow wells located an appreciable distance from the disposal area. These wells indicate much more consistent levels over time (i.e., limited, if any, impacts).

A comparison of the specific conductance versus sulfate was performed to determine if previous trends still exist. The data was sorted based on increasing sulfate concentrations. The results are shown on Figures 18 and 19. As can be seen, the linear relationship previously found for the compounds still exists, except for the highest concentration data points. Figure 19 excludes the highest data points for each monitoring session in the data set.

The correlation between boron levels and the sulfate levels, as shown on Figure 20, also indicates a linear relationship, but with a larger relative change in the boron concentrations as compared to the sulfate values.

The geophysical work presented in the November 15, 1989 report relates to the groundwater data presented for analysis. Table 6 lists the EM conductivity values and their corresponding well locations, sorted by increasing EM values.

The comparison of the EM data to the chemical results has previously been reported by Foth and Van Dyke to exhibit a linear relationship between EM and specific conductance and sulfate levels, based on a limited number of data points. This conclusion is not supported by the new data. As can be seen on Figure 21A, there appears to be no correlation between increasing EM values and the groundwater contaminant levels. In order to further evaluate whether this potential relationship exists, wells with EM values above 60 mmhos/meter (roughly the highest 50% of the readings) were plotted relative to potential contaminant source areas (Figure 21B). As can be seen, these wells are located both upgradient and downgradient of the evaporation ponds and disposal areas. Hence, no

E. DISCUSSION AND RECOMMENDATIONS

Water levels: Water elevations differ over the site by 75 feet (minimum of 1862.20, maximum of 1937.70). The locations of surface water and topography surface appear to control the groundwater flow. Water levels in a few wells have changed substantially (e.g., 3 to 5 feet) during the four months between measurements in 1989. Three wells showed increases of over 10 feet.

Contaminant Concentrations: In general, contaminant levels increased in the areas immediately down gradient of the surface impoundments and disposal areas.

Three compounds were detected above the MCL levels in the groundwater. These compounds were nitrate, selenium and fluoride.

The EM survey does not appear to conclusively correlate to contaminant levels. The results seen over the 1989 monitoring period may be influenced by drought conditions.

Surface Water: Water quality in Saylor Slough exhibited concentration levels similar to historical levels based on the general indicator parameters of sulfate and specific conductance. Levels of these parameters in Upper and Lower Samuelson Slough increased relative to historical levels. Drought conditions may have contributed, at least in part, to these increases in as much as these concentrations would be expected to increase as relatively more evapotranspiration occurs and less groundwater discharges.

The levels of sulfate and specific conductance in the South Ash Pond have decreased. Current data for the East Ash Pond is not available.

G. GENERAL

Services performed by the geotechnical and environmental scientists for this project have been conducted in a manner consistent with the level of care and skill ordinarily exercised by members of the profession currently participating in this area under similar budget and time restraints. Other than this, no warranty, expressed or implied, is made.

H. SIGNATURES

The preceding report was prepared by the following:

LeeAnn M. Hammerbeck
Hydrogeologist

Mark B. Larson
Supervisor, Waste Management Unit

Terrance J. Zich, P.E.
Branch Manager, North Dakota

If not already completed, the permittee shall record, a notarized affidavit with the County Registrar of Deeds to place a notation in the County's tract system specifying that this solid waste management site, as specified in the legal description, is permitted to accept solid wastes for disposal. This affidavit shall specify that another affidavit must be recorded upon the facility's final closure.

Upon closure, a second affidavit shall be recorded specifying any final details regarding the types of wastes disposed of at the site, as well as any final details regarding the site's location, construction, management, etc. The Department must be provided a copy of both affidavits certified by the Registrar of Deeds in the county in which the disposal site is located. These certified copies must be forwarded to the Department within thirty (30) days of their recorded dates or if notification has been formally completed prior to completion of this permit renewal application, a certified copy of said notification shall be fowarded with the completed application.

I certify that the information in this application is true, correct and complete to the best of my knowledge.

INTRODUCTION

This application is for a special use disposal permit for an already permitted facility (SU-033) at Coal Creek Station (CCS), a 1000 MW electric generating plant located near Underwood, North Dakota. Permit SU-033 expired in July, 1985, but was extended indefinitely by letter from the North Dakota State Department of Health (Department) dated August 20, 1985, pending further review by the Department. The facility in question is called the east ash pond (EAP) and has been used on and off since 1980 as a wet impoundment for the disposal of the by-products of combustion at CCS, namely bottom ash and flue gas desulfurization (FGD) sludge. (See Figure 1.)

Due to a combination of factors, including a high groundwater table, unfavorable geology, and an inadequate clay liner, the EAP has been taken out of service pending significant modifications, both in its construction and operation, which are the subject of this application.

Also subject to permit SU-033 is a separate, but adjacent facility called the south ash pond (SAP). Since these two facilities will no longer be used in the manner for which they were originally permitted (wet impoundments, permanent storage), and since they are each being redesigned and upgraded for different purposes, (EAP — dry, permanent disposal; SAP — wet, temporary disposal) it is proposed herein that separate permits be issued for these facilities. This application, however, will address only the EAP.

FIGURE 1
LOCATION MAP
COAL CREEK STATION

The SAP will be addressed in a subsequent application. However, in order to understand the overall plan for handling wastes in the future at CCS, it should be noted here for the benefit of reviewing agencies that the SAP has been emptied, partitioned and will be used in the future as a temporary storage or holding pond. One side will alternate as an active wet impoundment, receiving sludge and bottom ash from the plant, while the other side is dewatered prior to the wastes being hauled to the EAP or subsequent permanent disposal area. Currently, the western section of the SAP is receiving wastes from the plant.

The proposed modifications in the EAP include a significant addition of clay and spoils materials to most of the bottom which will serve to raise it to a level of at least five feet above the water table and which should also serve to provide a permeability coefficient in the liner of at least 1×10^{-7} cm/sec. The only exception is the southwest corner of the EAP which is partially filled with ash and sludge. This section of the EAP has favorable geology and the cost of removing the waste materials would be excessive. Therefore, it is proposed that it be dewatered and covered to control runoff and infiltration, prior to continued use as a dry landfill.

Based on a thorough study of all aspects of the situation, these physical and operational changes should minimize or eliminate further degradation of the groundwater. In fact, once these modifications are made, there should be a steady improvement in the groundwater quality in the area.

I. WASTE CHARACTERISTICS

A. Quantities (Foth & Van Dyke, 1987; Black & Veatch, 1988)

The solid wastes generated at CCS include fly ash, bottom ash and FGD sludge. Fly ash constitutes about 55 to 65 percent of the total ash produced during combustion. Over 99 percent of the fly ash produced during combustion is captured in the electrostatic precipitators for disposal. Historically, a large portion of the collected fly ash has been used as a reagent in the FGD system. Also, large quantities of fly ash have been sold for use in concrete. Fly ash which is not used as FGD reagent or sold, has been trucked off site and disposed of in specially designed pits located in mined areas north of the plant.

The remaining 35 to 45 percent of the ash forms into bottom ash or boiler slag. This material is sluiced together with the FGD sludge to the wet impoundments.

In 1988, CCS burned 6.8 million tons of lignite and operated at a plant capacity factor of about 85 percent. The following quantities of wastes were produced.

Material	Cubic Yards-1988	Cubic Yards/Day
Fly Ash	222,443	609
Bottom Ash	384,775	1054
FGD Sludge	522,694	1432
Total	1,129,912	3095

It should be noted here that a total volume of fly ash of 522,409 cubic yards was produced at CCS in 1988; however, of that volume 216,752 cubic yards were used as a FGD reagent and are included in the above FGD sludge numbers. Also not included in the fly ash quantities listed in the above table are 83,215 cubic yards that were sold. The volumes of bottom ash and FGD sludge are "wet" volumes assuming 25 percent and 50 percent moisture, respectively.

Since 1988 was a record year in terms of the quantity of lignite burned, and since an 85 percent plant capacity factor is near the maximum practical limit of operation for CCS, the volumes given here can be considered to be near the maximum amount of waste that can be generated at CCS in a year.

B. Physical Characteristics (Foth & Van Dyke, 1987; Black & Veatch, 1989)

Ash is the inorganic residue remaining either as fly ash or bottom ash after the lignite is burned. It originates chiefly from the mineral matter that was present in the unburned coal. Ash composition is a function of the type of coal burned, the combustion method and the emission control devices used. Typically, ash constitutes about 11 percent of the lignite by weight.

Bottom ash consists of angular particles with a porous surface texture that is normally gray to black in color. Boiler slag is composed of black angular particles having a glossy appearance. Table 1 contains an elemental analysis of CCS bottom ash.

TABLE 1

Lead	0.59	0.67	0.39	0.57	0.58	0.35
Zinc	0.02	0.02	0.11	0.02	0.02	0.02

NOTE: These samples were taken from one 55-gallon barrel of bottom ash collected for analysis. Bottom ash is not analyzed on a regular basis.

Fly ash produced at CCS is comprised of very fine particles, the majority of which are glassy spheres, with the remainder being crystalline matter and carbon. A minerological analysis of the fly ash reveals that its principal chemical constituents are silica (SiO_2), lime (CaO), and alumina (Al_2O_3). See Table 2 for the complete analysis. Table 3 contains a trace element analysis of CCS fly ash conducted in 1979 (sample 3) and 1980 (samples 1 and 2).

The FGD system at CCS is a combination lime/fly ash system. This system is capable of using lime only or a combination of lime and fly ash as a reagent. A thorough study of these wastes was conducted in November 1987 by Foth & Van Dyke, a geosciences consulting firm. The materials, located in the SAP and subsequently hauled to a permanent disposal site north of CCS, were visually classified in a laboratory according to the relative proportions of the major components: fly ash, bottom ash and FGD sludge. This was done in order to determine whether a reasonable correlation existed between the physical and chemical properties of the ponded materials. Six types were identified.

Type 1 Bottom ash with less than 20 percent fly ash and/or FGD sludge.

Type 2 Bottom ash with 20-50 percent fly ash and/or FGD sludge.

Type 2T Bottom ash with 20-50 percent fly ash and/or FGD sludge — thixotropic.

Fluorine	220	220	—
Boron	1078	1095	210
Beryllium	4.9	4.9	7.5

Type 2S Bottom ash with 20-50 percent fly ash and/or FGD sludge — soft.

Type 3 Material with greater than 50 percent fly ash and/or FGD sludge.

Type 3T Material with greater than 50 percent fly ash and/or FGD sludge — thixotropic.

Approximately one-third (33 percent) of the material in the SAP was judged to be relatively clean bottom ash or Type 1 material. Another one-fifth (20 percent) of the material was estimated to be Type 2 material. Type 3 material made up the remaining 47 percent of the sediments. Approximately 15 percent of the Type 2 material and approximately 50 percent of the Type 3 material was thixotropic.

C. Chemical Characteristics (Foth & Van Dyke, 1987)

As a part of the above study, 88 samples were analyzed for various chemical parameters. The total included 87 samples from borings and one fresh FGD sludge sample. All of the samples were analyzed for total and leachable arsenic, cadmium and boron. Sulfate, chloride and pH were measured in the leachate solutions of these samples. Eight selected samples were also analyzed for total and leachable magnesium, sodium, calcium, potassium and lead. Fluoride, total dissolved solids and specific conductivity were also measured in the leachate solutions of the select samples. Digestion and analyses for the total constituents

were conducted following Standard Methods. Leaching analyses were performed according to ASTM Method D 3987-81 as requested by the Department. All of the analyses were performed in the Foth & Van Dyke Chemistry Laboratory in Green Bay, Wisconsin. A complete report is on file at the Department.

The results of these analyses indicate that the values of total and leachable cadmium and leachable selenium were below the detection limits of the methods employed. All but four of the total selenium values were below the detection limit and the four that were measured were at detection limit values. All but four of the leachable arsenic values were below the detection limit, and the four with measurable values had concentrations that were only slightly above the detection limit. These data indicate that, although metals are present in the samples, the metals do not leach out of the ash material under conditions found in the pond.

The pH of the leachate solutions was remarkably consistent from sample to sample. Fly ash reacts with water, leading to immediate dissolution of the alkalis and the alkaline earths from their oxide forms within the ash grains, subsequently forming hydrated ions. These reactions result in the high pH which is observed in the ash pond. The average pH value is approximately 10.2 units. An elevated pH level in a reaction stable environment, such as the SAP, tends to minimize leachability of the metals that are present.

FGD sludge reacts with the water in the pond releasing considerable quantities of sulfate and calcium. The principal components of FGD sludge are generally calcium sulfate and calcium carbonate. Upon reacting with water in the ash pond, the calcium sulfate becomes hydrated forming the mineral phase gypsum. The presence of the FGD sludge in the basin has a limiting effect on the leaching of materials from the fly and bottom ashes, since the high concentrations of sulfate tend to inhibit the dissolution of the ash. In addition, the high sulfate makes the calcium sulfate minerals less soluble than they would otherwise be due to the common ion effect.

Total boron concentrations varied between samples, and when these values were grouped according to the type of material analyzed, differences in the mean values between the groups were observed. As shown on Table 4 the Type 1 materials have the highest total boron (317 mg/kg) and the Type 3T have the lowest total boron concentrations (220 mg/kg). T-test comparisons between the mean values indicated that the differences between the groups is significant. Probabilities that significant differences exist between Type 1 and Type 2's are 99 percent, between Type 2's and Type 3 are 81 percent, and between Type 3 and Type 3T are 92 percent.

Leachable boron concentrations vary widely between samples. There were no significant differences between the means of the grouped data. However, leachable boron exhibits a distributional pattern for the highest concentrations. Those samples collected near the southern and

TABLE 4

Mean Concentrations

Material	No. Samples	Total Boron (mg/kg)	Total Arsenic (mg/kg)	Leachable Chloride (mg/l)	Leachable Sulfate (mg/l)
Type 1	22	317 ± 62	45.4 ± 18.8	17.4 ± 11.4	1346 ± 547
Type 2, 2S and 2T	22	264 ± 71	57.1 ± 21.6	27.8 ± 16.5	1750 ± 153
Type 3	18	240 ± 42	80.7 ± 21.0	29.1 ± 19.7	1695 ± 433
Type 3T	25	220 ± 31	94.2 ± 19.1	36.5 ± 22.8	1806 ± 259

Comparison of Statistical Probability by Material Type:

1:2	99%	>93% among all types	1:2 98%	1:2/3 99%
2:3	81%		2:3 No diff.	2:3 No diff.
3:3T	92%		3:3T 83%	3:3T No diff.

Source: Foth and Van Dyke, 1987

western borders of the pond and many of those collected at, or near, the base of the accumulated sediments contained relatively high concentrations.

Total arsenic concentrations when grouped by material type showed considerable differences in mean values as shown in Table 4. Type 1 materials have the lowest total arsenic concentrations (45.4 mg/kg) and Type 3T the highest (94.2 mg/kg). T-tests performed on the total arsenic calculations revealed that there is a 93 percent, or greater, probability that the differences between the mean values is significant.

Leachable chloride concentrations differed between samples. Mean values of the concentrations grouped according to type of material leached are shown in Table 4. Type 1 materials have the lowest leachable chloride concentrations (17.4 mg/kg) and the Type 3T have the highest (36.5 mg/kg). T-tests performed on the means indicate that there is no significant difference between the Type 2's and the Type 3 means. There is a 98 percent probability that the difference between the Type 1 and the Type 2's is significant, and a 83 percent probability that the differences between the Type 3 and the Type 3T are significant.

Leachable sulfate concentrations, when grouped according to type of material leached, have somewhat differing mean concentrations as shown in Table 4. There are no significant differences in the mean leachable concentrations among Type 2 (1,750 mg/l), Type 3 (1,695 mg/l) and Type 3T (1,806 mg/l) materials. A significant difference (99 percent probability) does exist between the mean concentrations in Type 1 material (1,346 mg/l), which are the lowest, and the other materials.

Selected ash samples and fresh FGD sludge were analyzed for total and leachable alkalis, alkaline earths and lead. Leachable fluoride, total dissolved solids and specific conductivity were also measured. The results are presented in Tables 5 and 6.

The data show that the pond sample at location 458-1 is physically and chemically similar to the fresh FGD sludge. However, the ash contained lower leachable fluoride, total dissolved solids and had lower leachate conductivities than the fresh FGD sludge. There were no differences in total lead concentrations between the ponded ash materials and the fresh sludge. Leachable lead concentrations were below the detection limit for all samples.

The total and leachable sodium concentrations were lower in the ponded samples than in the fresh sludge. The total magnesium concentrations were approximately the same in all of the materials, but the leachable magnesium concentrations were much lower in the sediments than in the sludge. Total calcium and potassium concentrations in the sediments were lower than the sludge, but leachable calcium was greater and leachable potassium much greater in the sediments than in the sludge. High levels of calcium are typical for wastes derived from the combustion of Western lignite and sub-bituminous coals.

Western ashes commonly develop significant strength after several months of burial, especially if the burial is in an unsaturated site. This is due to the cementitious nature of these high calcium materials. The materials in the cement are likely to include hydrous calcium sulfate,

calcium and magnesium carbonates and hydrous iron oxides. Fly ash tends to be pozzolanic, a special type of self-cementation. During this process, hydrous aluminosilicates form, especially the mineral ettringite. The leaching potential of these materials greatly decreases once cementitious reactions have occurred. Some of the sediment samples from the pond were found to be partially cemented.

In summary, bottom ash and FGD sludge generally exhibit similar potential for leaching. Boron and sulfates exhibit the greatest leachability potential of the parameters tested. Arsenic, selenium, cadmium and lead are bound up in the ash materials and are immobilized because of the high pH level, which is evenly distributed throughout most of the ash material.

The analysis of these materials is provided as representative of the physical and chemical characteristics of the materials to be deposited in the EAP in the future. It should be noted, however, that some variations are possible — both in the quantities and the chemical characteristics of the various wastes produced — depending on the amount of fly ash that is used as a reagent in the FGD system. The range of quantities of fly ash used as a reagent can vary from zero to as much as 40 percent of the fly ash produced at CCS. It is further contemplated that dry fly ash may also be deposited in the EAP in the event that it is not used as a reagent, or sold or trucked to the mine pit disposal area. Thus, this application specifically includes fly ash as a waste intended for disposal in the EAP.

II. LOCATION INFORMATION

Coal Creek Station is located in on a 2560 acre site in McLean County, North Dakota. A composite U.S.G.S. Quadrangle map showing its location has been developed and enclosed as Figure 2. The EAP is located in section 16, Township 145N, Range 82W. An aerial photograph showing the EAP and the SAP is included in this application as Figure 3. A detailed site map is included as Figure 4.

Since the EAP is an already permitted solid waste disposal site, no change in local zoning is anticipated.

III. GENERAL GEOLOGY AND HYDROLOGY

A. Geology — Overview (BARR Engineering, 1982)

Coal Creek Station is located in an area underlain by the Fort Union Group of sedimentary rocks. These are poorly consolidated silts, clays and sands interbedded in the upper non-marine units with mineable lignite. The only marine formation that subcrops in the area and the oldest is the Cannonball formation. Figure 5 shows the locations of regional cross sections. Figure 6 shows the Cannonball formation. It and the overlying Slope formation are encountered only at the base of deep bedrock valleys. The Slope formation is similar to the upper two nonmarine units, the Bullion Creek and Sentinel Butte formations. The nonmarine sands and the fractured lignites of this sequence are water bearing.

Bedrock topography is thought to reflect preglacial drainage when the Missouri River flowed toward Hudson Bay. The original patterns have been modified, however, due to the tremendous effect of the glaciers on the directions of streamflow.

Bedrock is buried by the Coleharbor formation, an unconsolidated unit of glacial drift. These sediments, which completely fill many bedrock valleys, consist of sandy, silty, clay tills, sand and gravel outwash, and silt and clay lake deposits. In a few places the Coleharbor formation is overlain by the Oahe formation which is primarily made up of recent alluvium.

BARR ENGINEERING

B. Geology — Site (BARR Engineering, 1982)

The CCS occupies sections 8, 9, 16, and 17 of Township 145N, Range 82W. The underlying Cannonball formation is estimated to be 270 feet thick. Its contact with the Slope formation is probably around elevation 1600. The Slope here is approximately 50 feet thick. The overlying Bullion Creek is 150 to 190 feet thick. Its contact with the Sentinel Butte formation is at elevation 1840. The Sentinel Butte outcrops in the southwest quarter of section 17.

The bedrock topography is dominated across the site by a deep valley. The floor of this valley, referred to as the Weller Slough Valley, may slope toward a now-buried channel of the Knife River, east of Washburn.

The Weller Slough Valley is over 365 feet deep and filled with sediments of the Coleharbor formation. There are three tills interbedded with lake deposits and a thick sand and gravel sequence. The latter comprises the Weller Slough aquifer. It is over 100 feet thick in places and is located near the base of the valley. (See Figures 6-8.)

Some sediments of the Oahe formation are located in a linear deposit oriented north-south through sections 9 and 16. The fine alluvium around Samuelson and Weller Sloughs is also included in this formation.

C. Hydrogeology — General (BARR Engineering, 1982)

Work done in the Falkirk Mine area has shown that within bedrock, groundwater flow is predominantly vertically downwards through the claystone and siltstone beds that act as aquitards. In the more permeable lignite and sand beds, groundwater is thought to flow horizontally toward the Weller Slough and Coal Lake Coulee channels. The Cannonball formation is considered the regional confining stratum, separating the shallower aquifers from the deep bedrock aquifers.

The sands of the Sentinel Butte and Bullion Creek formations are reported to have permeabilities on the order of 10^{-4} cm/sec. The average permeability of the lignite beds in the Sentinel Butte formation is on the same order. The clay and silt aquitards have a mean permeability of 10^{-6} cm/sec.

The tills exhibit a wide range of permeabilities also. Unfractured till shows a range from 10^{-7} to 10^{-8} cm/sec. The permeability of fractured till may be as great as 10^{-4} cm/sec. The sand and gravel units in the valley are reported to have a mean permeability of 10^{-3} cm/sec.

D. Weller Slough Aquifer

The thickness of the Weller Slough aquifer varies from 28 to more than 109 feet in the vicinity of CCS. As mentioned above, confined conditions in the aquifer indicate that the glacial till overlying the aquifer is significantly less permeable than the aquifer sands and

gravels. Because the overlying strata are relatively impermeable, it is likely that significant recharge to the Weller Slough aquifer is from bedrock units thought to be discharging at the valley wall interface. Specifically, the Hensler sand and Bullion Creek formation and the entire Slope formation are in direct contact with the sand and gravel units of the Weller Slough aquifer. It has been reported that the Hensler sand may be a regional groundwater sink; however, groundwater movement from the Weller Slough aquifer to the Hensler sand would be unlikely.

Precipitation may infiltrate the upper till soils under certain conditions. However, after evaporation, most of the water is thought to accumulate as runoff to the sloughs. Leakage from the sloughs does not seem to contribute significantly to the recharge of the Weller Slough aquifer. (Groenewald, et. al. 1979)

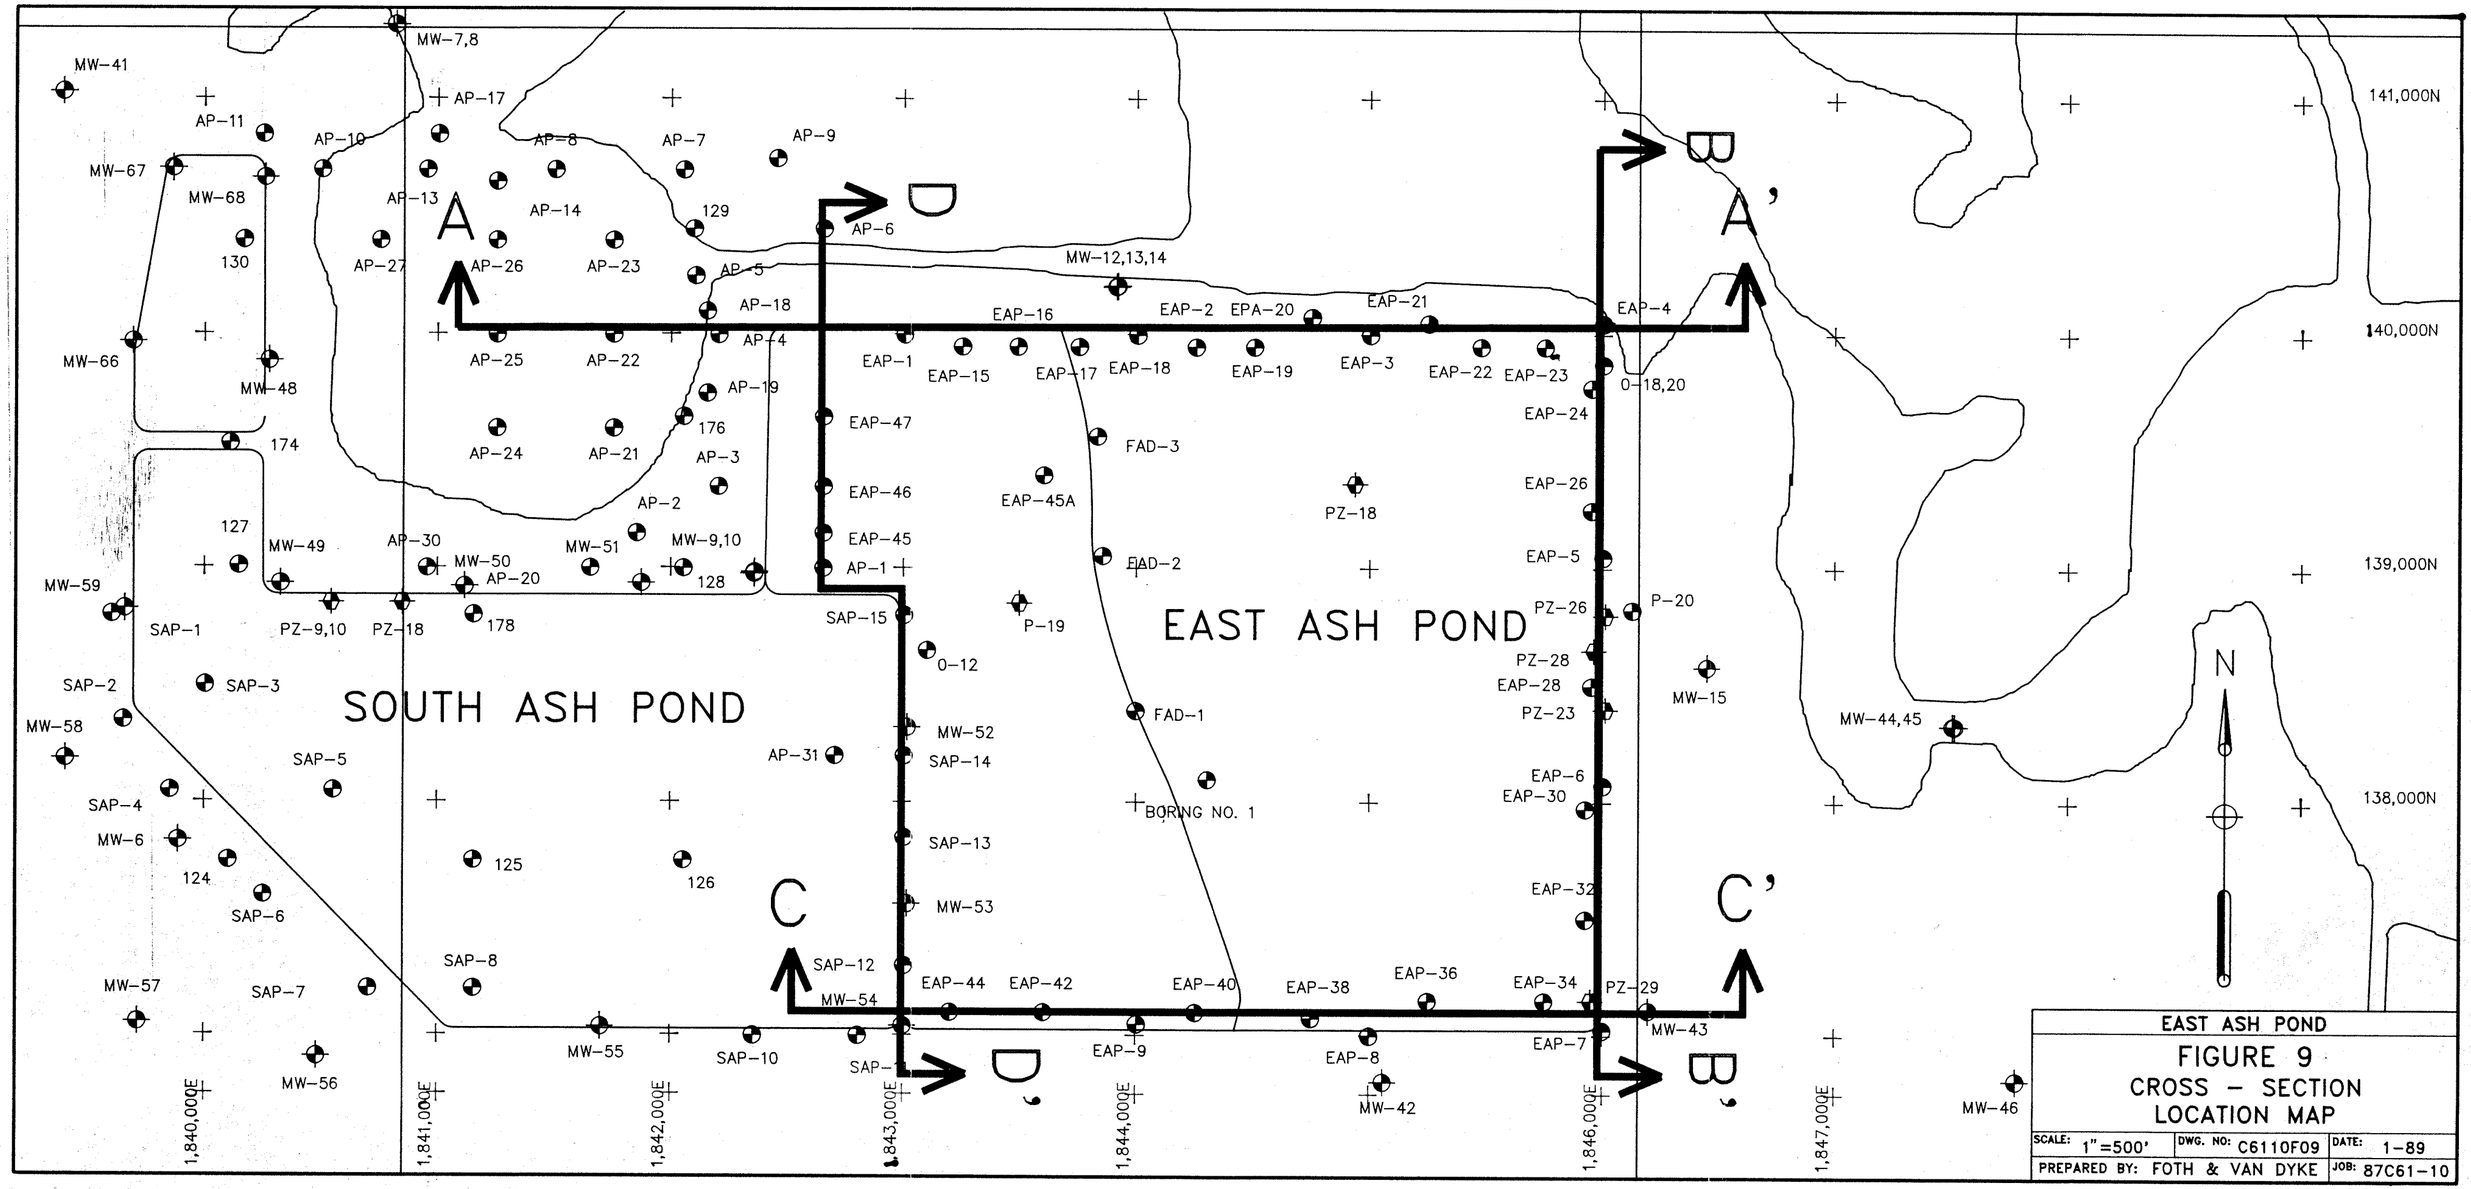
E. Hydrology

The surface water of interest in the area of CCS includes Samuelson Slough, Weller Slough, Saylor Slough, Gradin Slough and the Legal Drain system. These wetlands and the legal drain represent the confluence of three regional water sheds; one which drains into Weller Slough, one which drains into Samuelson Slough, and the Coal Lake Coulee which drains into Saylor Slough. In addition, the Falkirk Mining Company has been pumping large quantities of mine pit water into the Legal Drain which flows to Samuelson Slough. Weller Slough flows into Samuelson

Slough, and Samuelson Slough, in turn, flows into Saylor Slough. Saylor Slough flows to Gradin Slough, which flows to the Missouri River, six miles south of CCS.

These wetlands are also influenced by the upper level aquifer. This is discussed in some detail in the next section.

IV. SITE SPECIFIC GEOLOGY AND HYDROLOGY



Detailed hydrogeological studies have recently been conducted by Foth & Van Dyke to augment previous efforts to better understand the conditions at the CCS site and to provide a basis for the mitigation of the current groundwater conditions. The results of these studies and analysis are presented in this section.

Site Geology

The site geology indicates near-surface silty clay and sandy clay till with interbedded sand lenses. The Oahe formation, mentioned above in the general discussion of the area geology, is the uppermost unit and is found in some parts of CCS. The surficial deposits of this formation are, by definition, the result of post-glacial drainage patterns. It is reported to be fine to coarse alluvium in a linear deposit going north-south through the middle of sections 9 and 16. This relatively high permeability unit is believed to be beneath parts of the EAP.

The next lower unit is the Napoleon drift of early Wisconsin age. This uppermost glacial unit is typically 15-20 feet of cohesive silty, sandy, lignitic till which is yellow to brown. The gray pre-Wisconsin Mercer drift is deposited below the Napoleon drift.

The subsurface geology in the vicinity of the EAP can best be shown with geological cross sections. The locations of the cross sections are shown on Figure 9. Geological cross sections A-A', B-B', C-C' and D-D' are provided as Figures 10, 11, 12 and 13, respectively.

Cross section A-A' (along the north dike) shows an extensive sand lens within the Napoleon glacial unit. A significant sand-filled erosional feature also cuts through both the Napoleon and Mercer glacial units which is interpreted to be the Oahe formation. Cross sections B-B' and C-C', along the east and south dikes, respectively, also show extensive sand lenses within the clayey till. A less extensive sand lens is shown on cross section D-D' along the west dike separating the EAP and the SAP. The sand lenses are highly permeable avenues for horizontal movement of water.

Sand seams of an inch or more in thickness have also been reported in the clayey till. The soil boring methods which have been used, flight augers and/or split spoon sampling at 5-foot intervals, do not allow mapping of these thin sand layers. The sand seams can, however, provide significant horizontal migration paths for water.

The geology of the area provides several mechanisms for potential vertical seepage through the bottom of the EAP. They are: 1) fractured till; 2) exposed sand; 3) loss through bottom soils of moderate permeability, and 4) seepage through test borings which have been improperly abandoned. All of these conditions present mechanisms for vertical migration of water through the pond bottom.

Fractured till is known to exist in the area of CCS and is a significant mechanism for vertical water movement. The effectiveness of this phenomenon may have been modified, however, during liner repair work in the spring of 1980. The project involved re-working some of the bottom

materials and placing additional clayey materials in other areas. Vertical fractures in the till can provide significant conduits for water to move from the pond downward into the highly permeable sand seams and lenses which are present beneath the EAP.

Exposed sand has been reported in the bottom of the EAP, most notably during the summer of 1979. This permeable material would allow access to more extensive sand lenses within the till. Records from 1980 show that approximately 118 acres of the EAP were judged to have inadequate clay for a liner. Liner modifications were made that same year to cover the exposed sand areas.

More than 200 shallow grid borings and more than two dozen deep borings have been drilled through the bottom of the EAP. Records of abandonment of the holes by deliberate and extensive filling and compaction are unknown. Many of the borings may have been partially sealed near the surface during liner modifications in the spring of 1980. The liner work is believed to have covered approximately 118 acres of the pond, which leaves the remainder of the 220 acre pond with potentially exposed improperly abandoned bore holes. The bore holes, if not filled with material of a permeability equal to or less than the native material, can provide a significant vertical pathway for water movement.

The significance of the above-listed potential vertical seepage mechanisms can be recognized in relation to a near-surface sand thickness map, Figure 14. The Sand Isopach Map shows the thickness of sandy material found near the surface of the pond bottom. The map

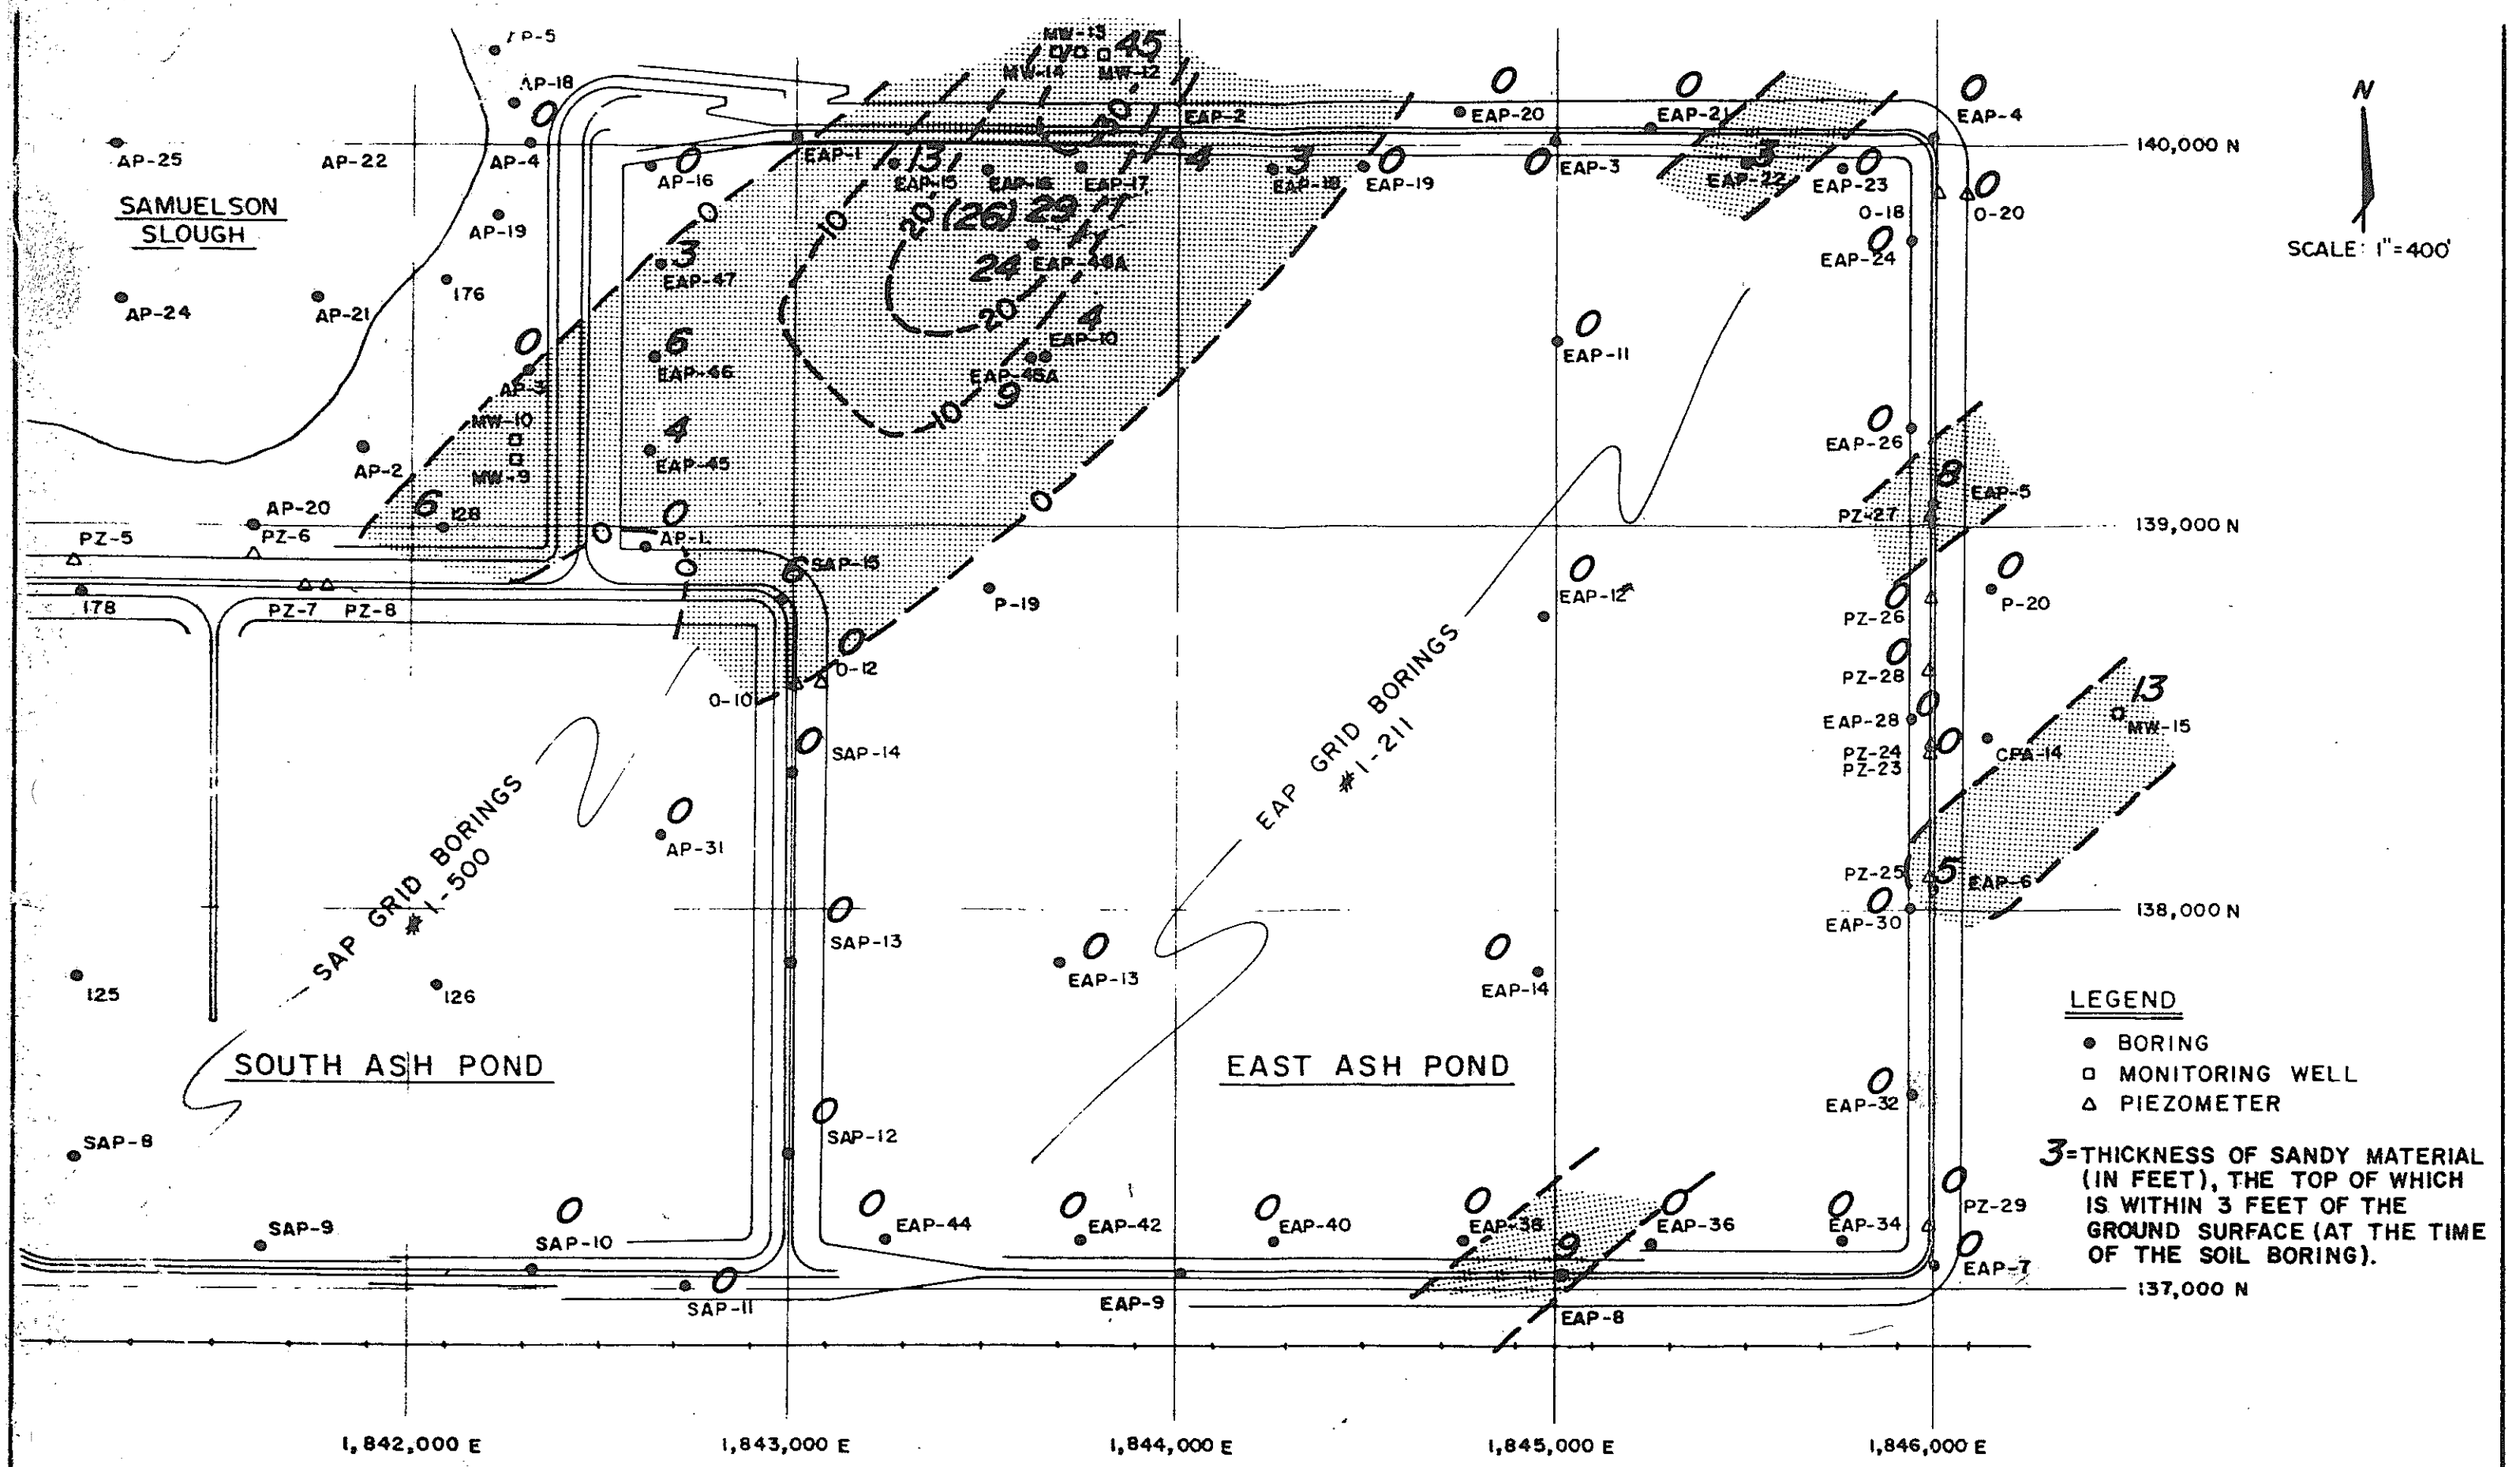

Figure 14

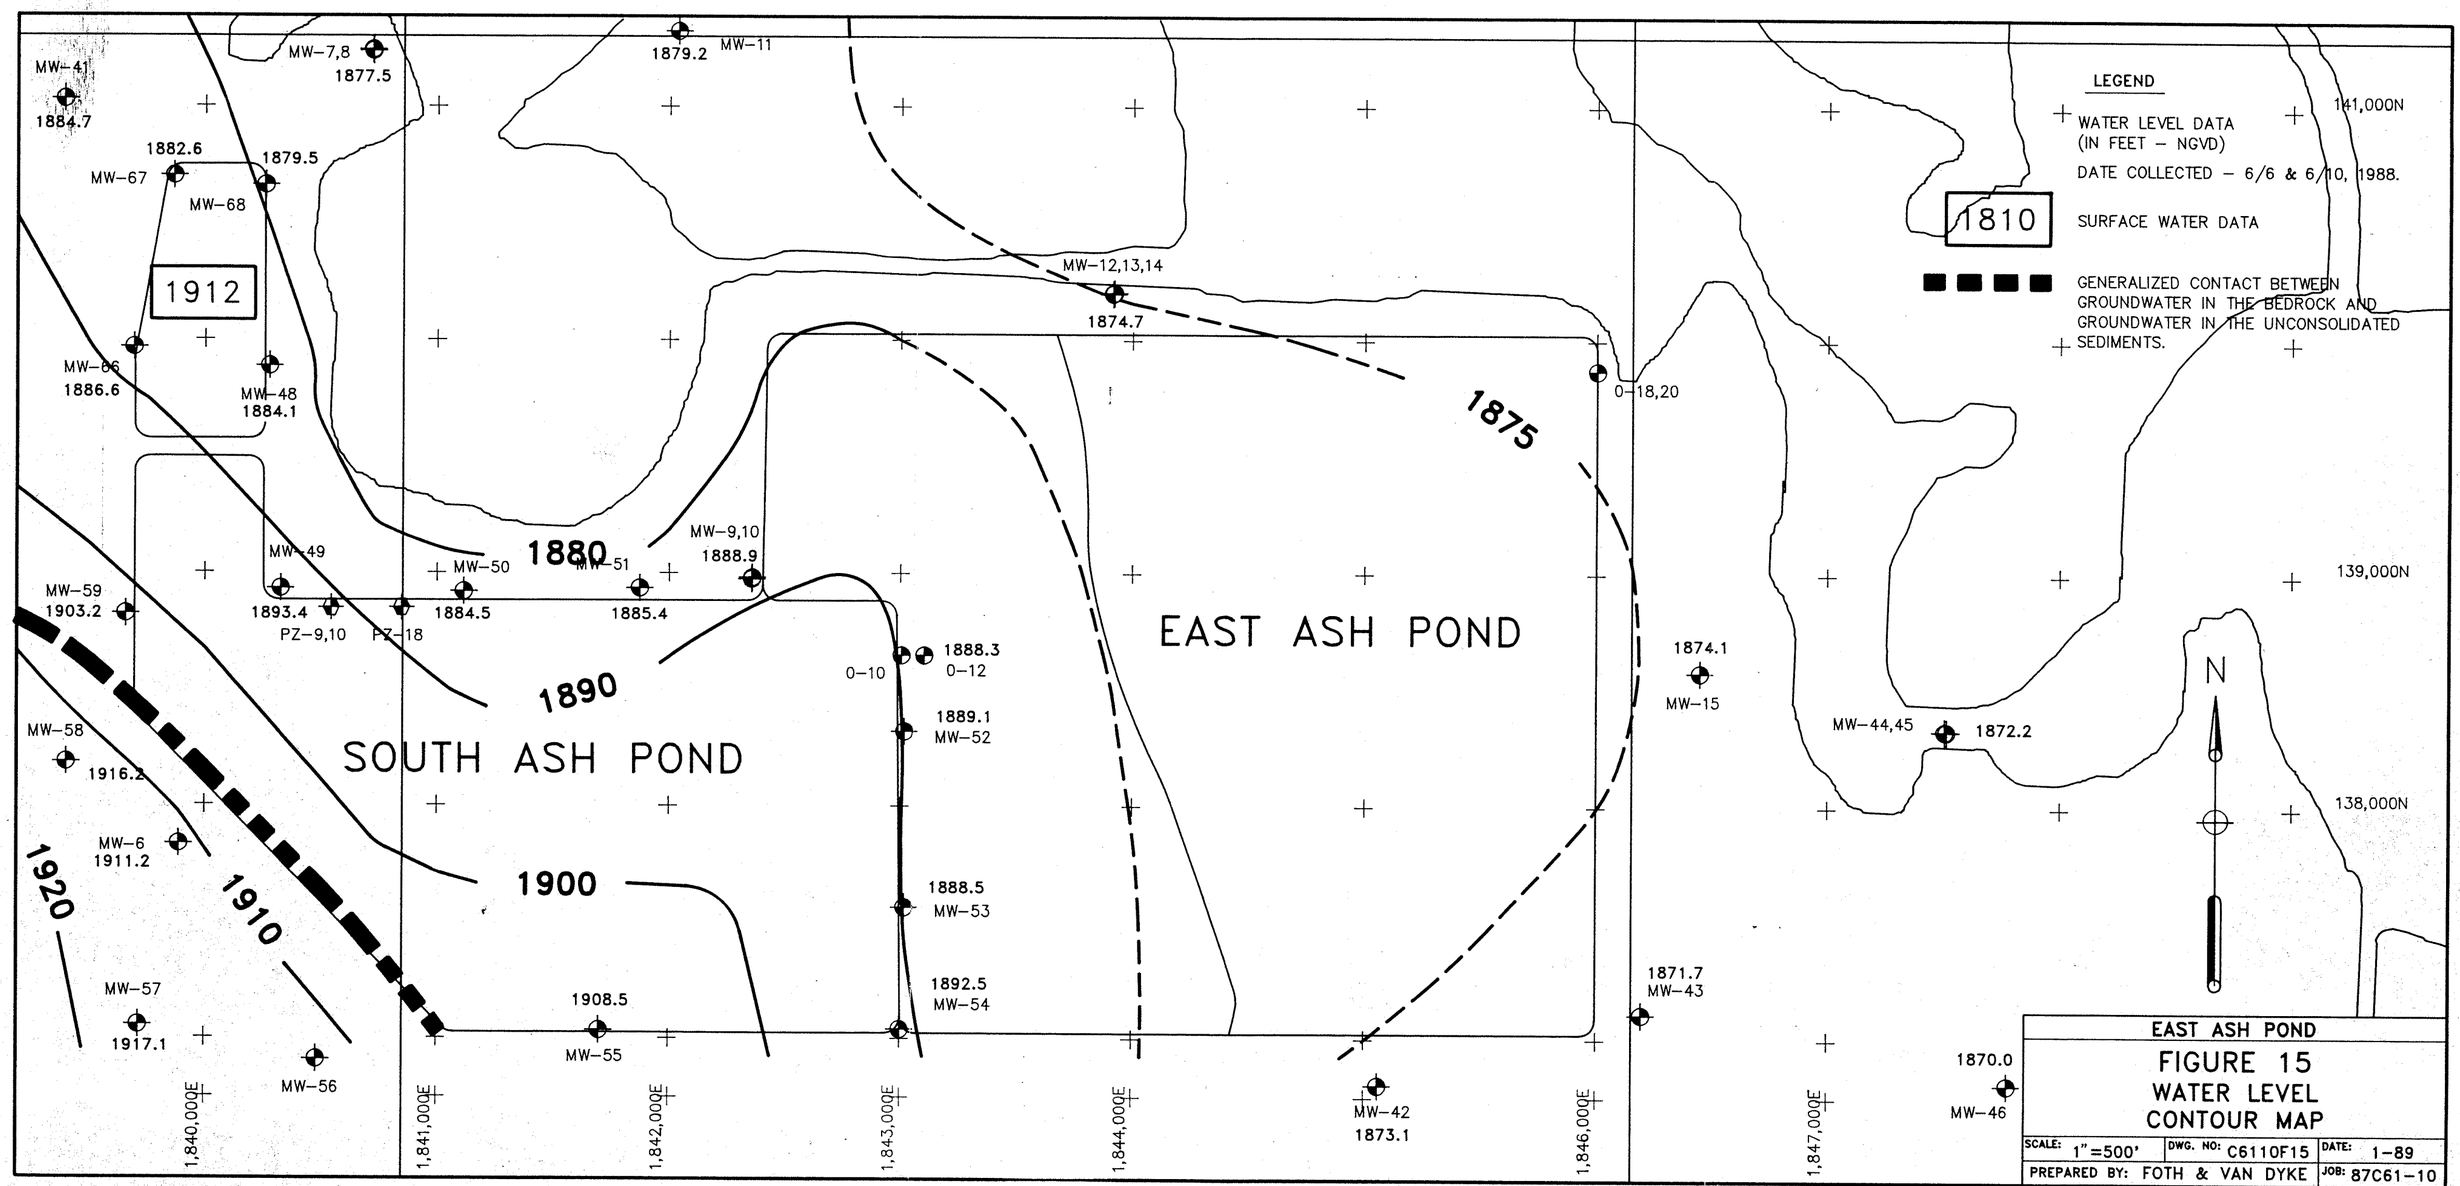
EAST ASH POND STUDY	E.A. HICKOK & ASSOCIATES HYDROLOGISTS - ENGINEERS MINNEAPOLIS - MINNESOTA	MAY 1985
SAND ISOPACH MAP		6

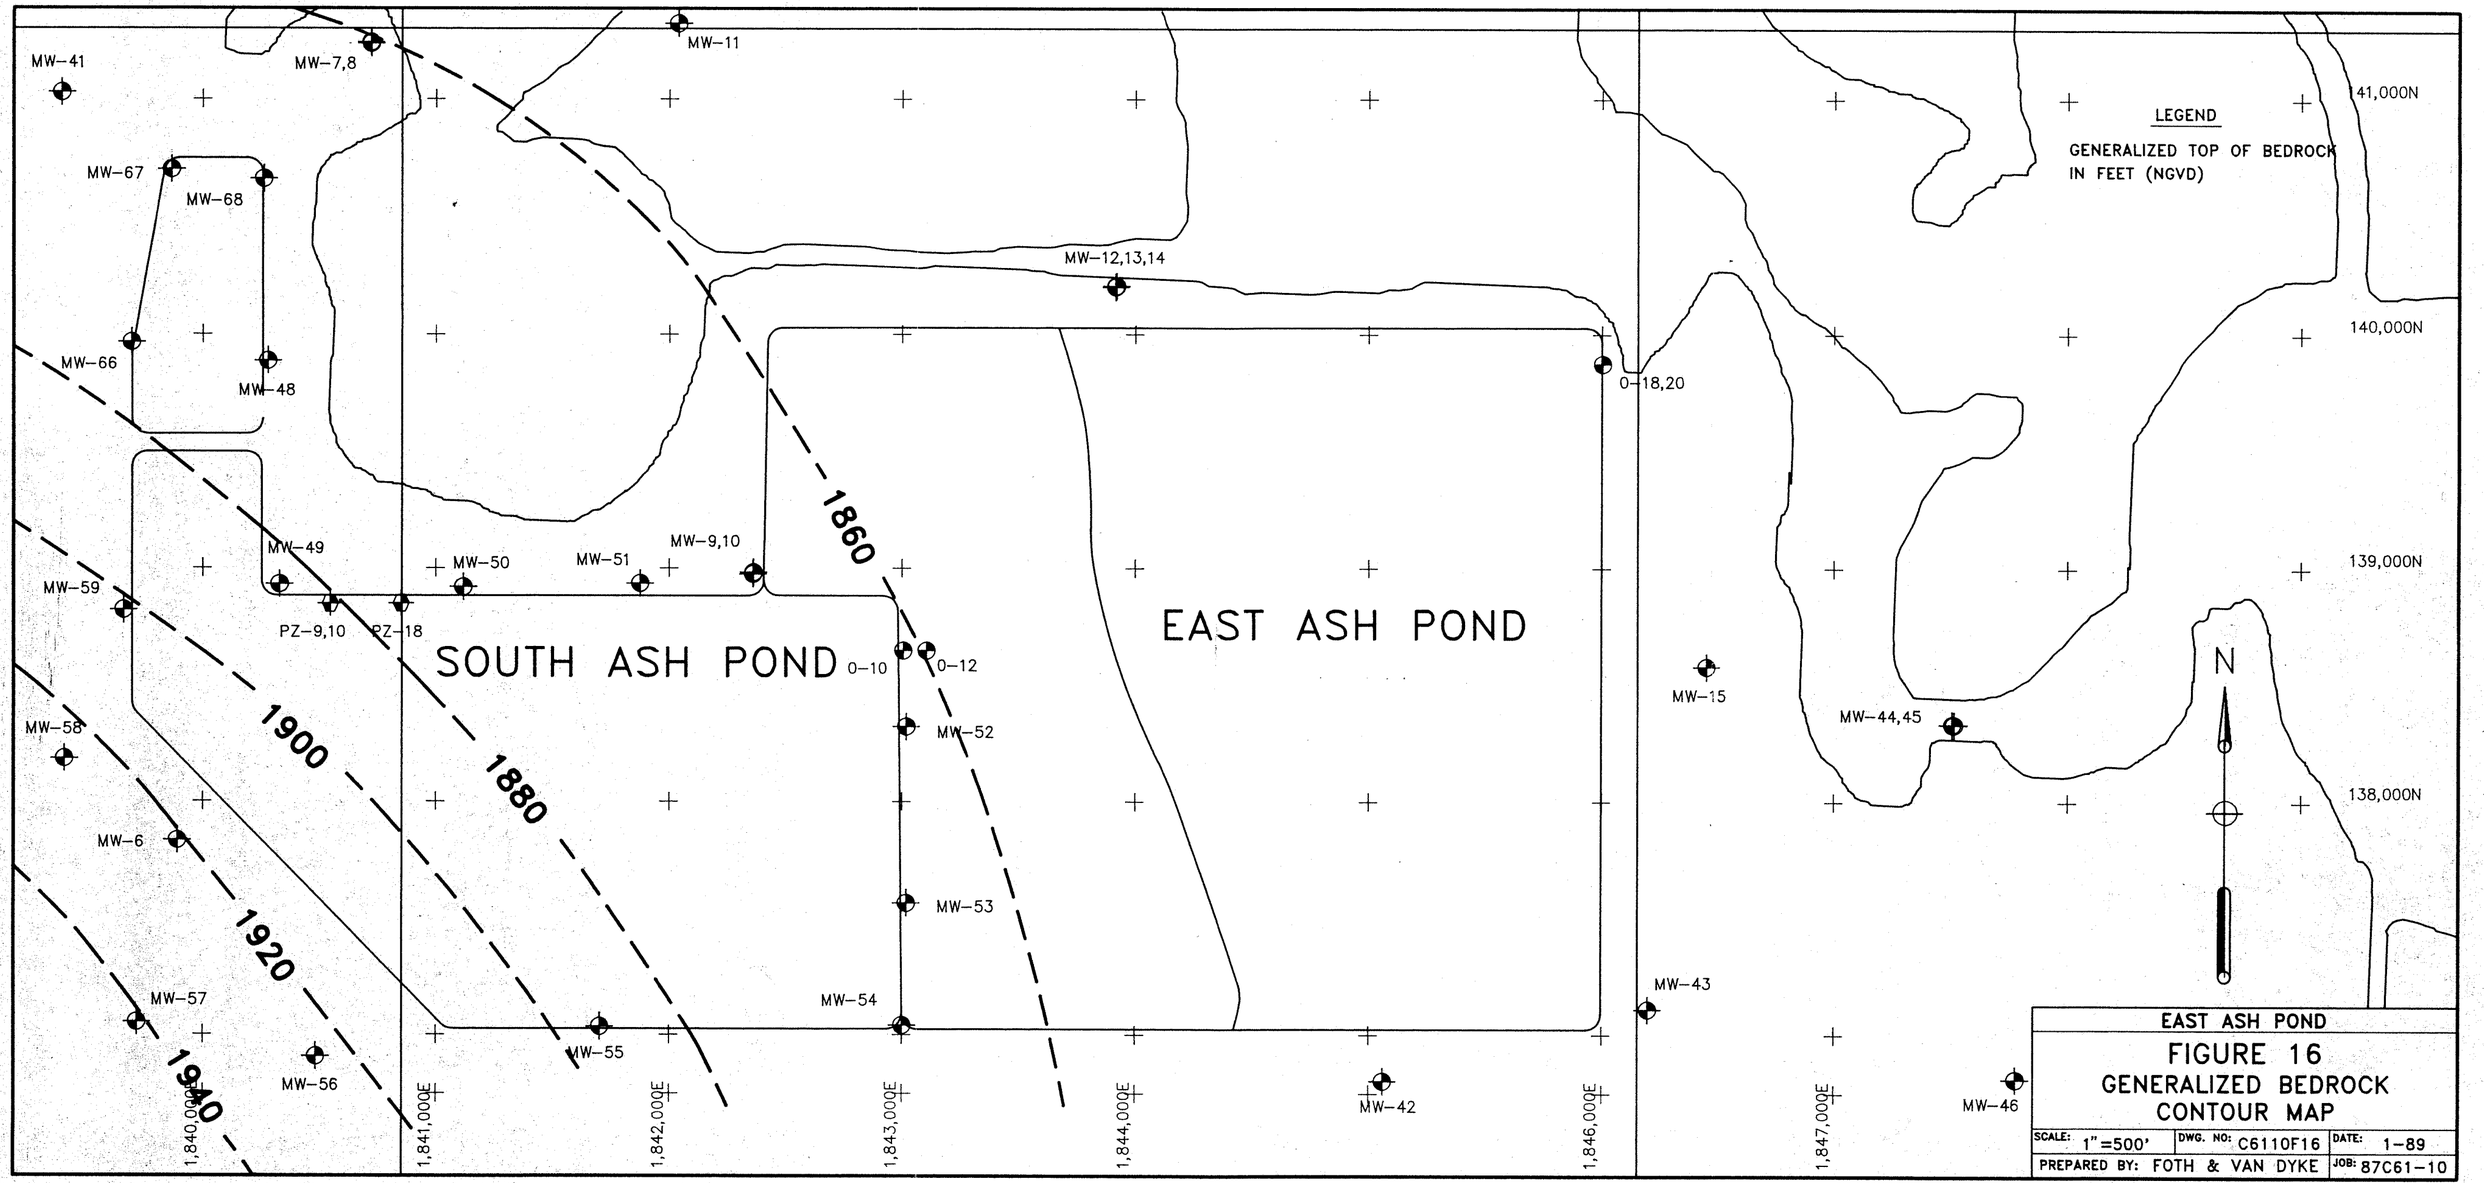


locates sand deposits which are within three feet of the bottom of the pond (at the time of drilling). This map illustrates that minimal vertical seepage depth is necessary to intersect significant sand lenses and sand seams capable of providing horizontal water migration beyond the EAP dikes.

The largest sand lens, probably the Oahe formation, is located in the northwestern part of the EAP. Significant sand lenses are also recognized beneath the east and south dikes. Other unrecognized sand lenses and sand seams may be present throughout the EAP.

B. Hydrogeology and Groundwater Flow Pattern

According to recent studies conducted by Foth & Van Dyke, regional groundwater flow in the vicinity of CCS is a subtle expression of the ground surface topography which is influenced by the configuration of the eroded bedrock. A water level contour map is presented as Figure 15. The groundwater contours approximate the bedrock contours shown on Figure 16, except where locally affected by other factors, such as mounding beneath ponds. The water in the uplands is within the poorly consolidated bedrock while the groundwater in the lowlands is found in the glacial till. An approximation of the point of transition between bedrock and glacial till regimes is shown on Figure 15.



Groundwater travels from elevated recharge areas toward several stream valleys and lowlands which ultimately discharge into the Missouri River.

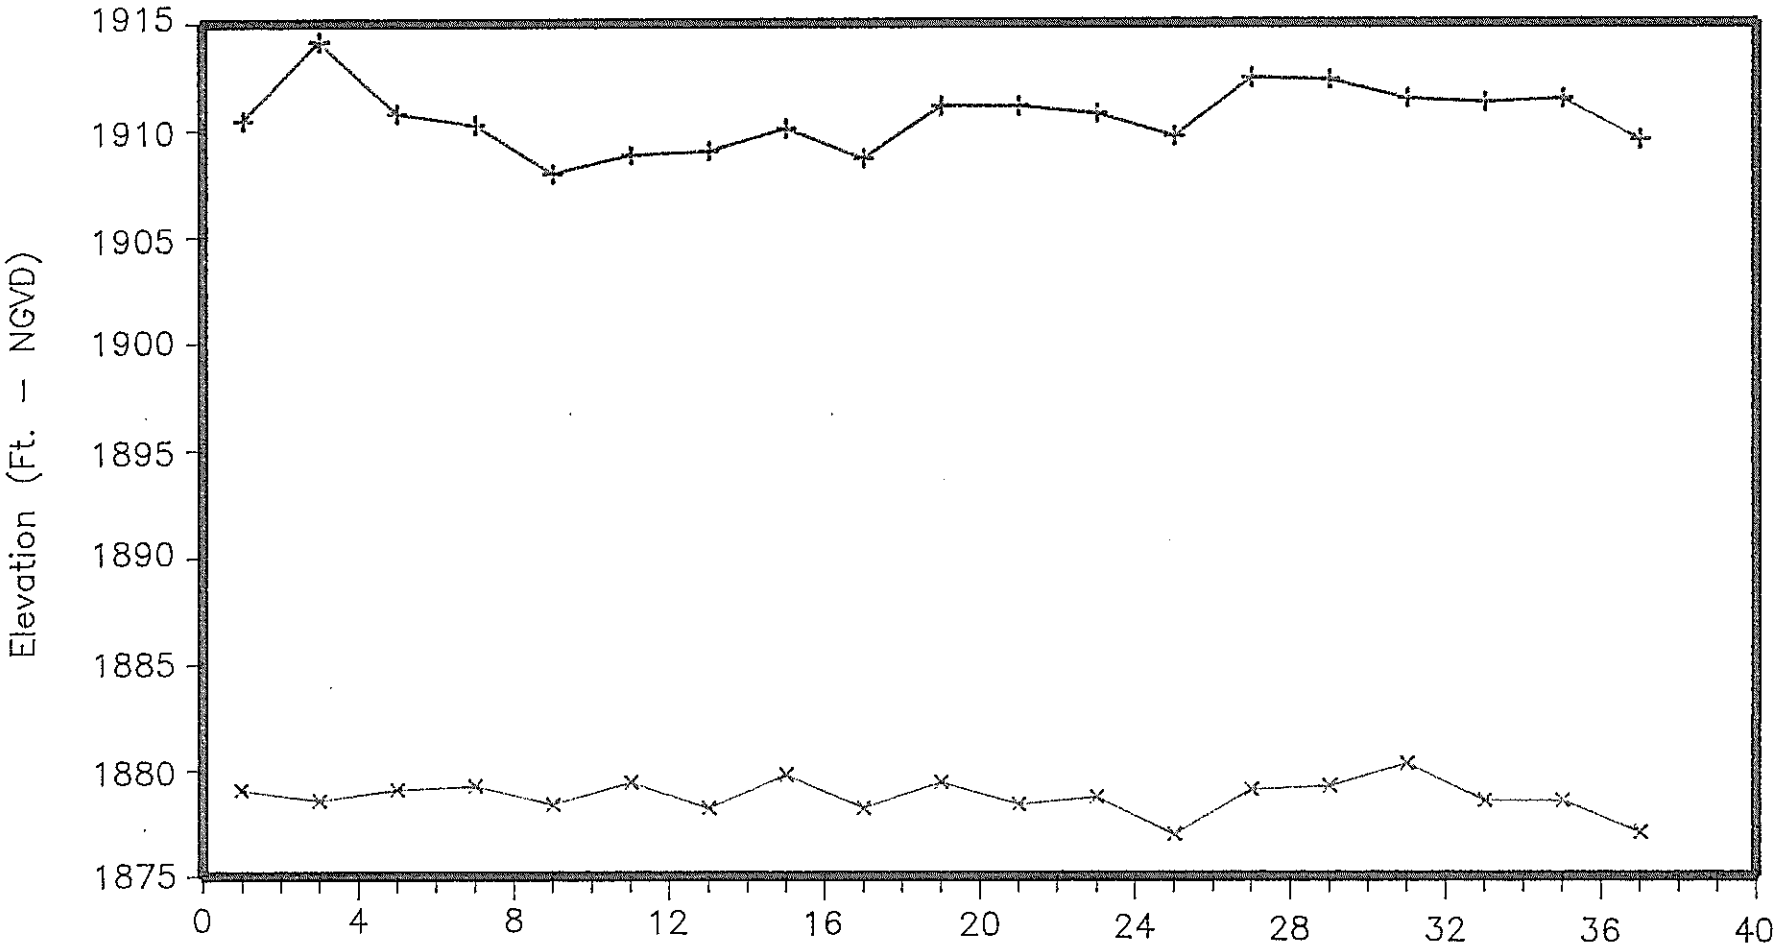
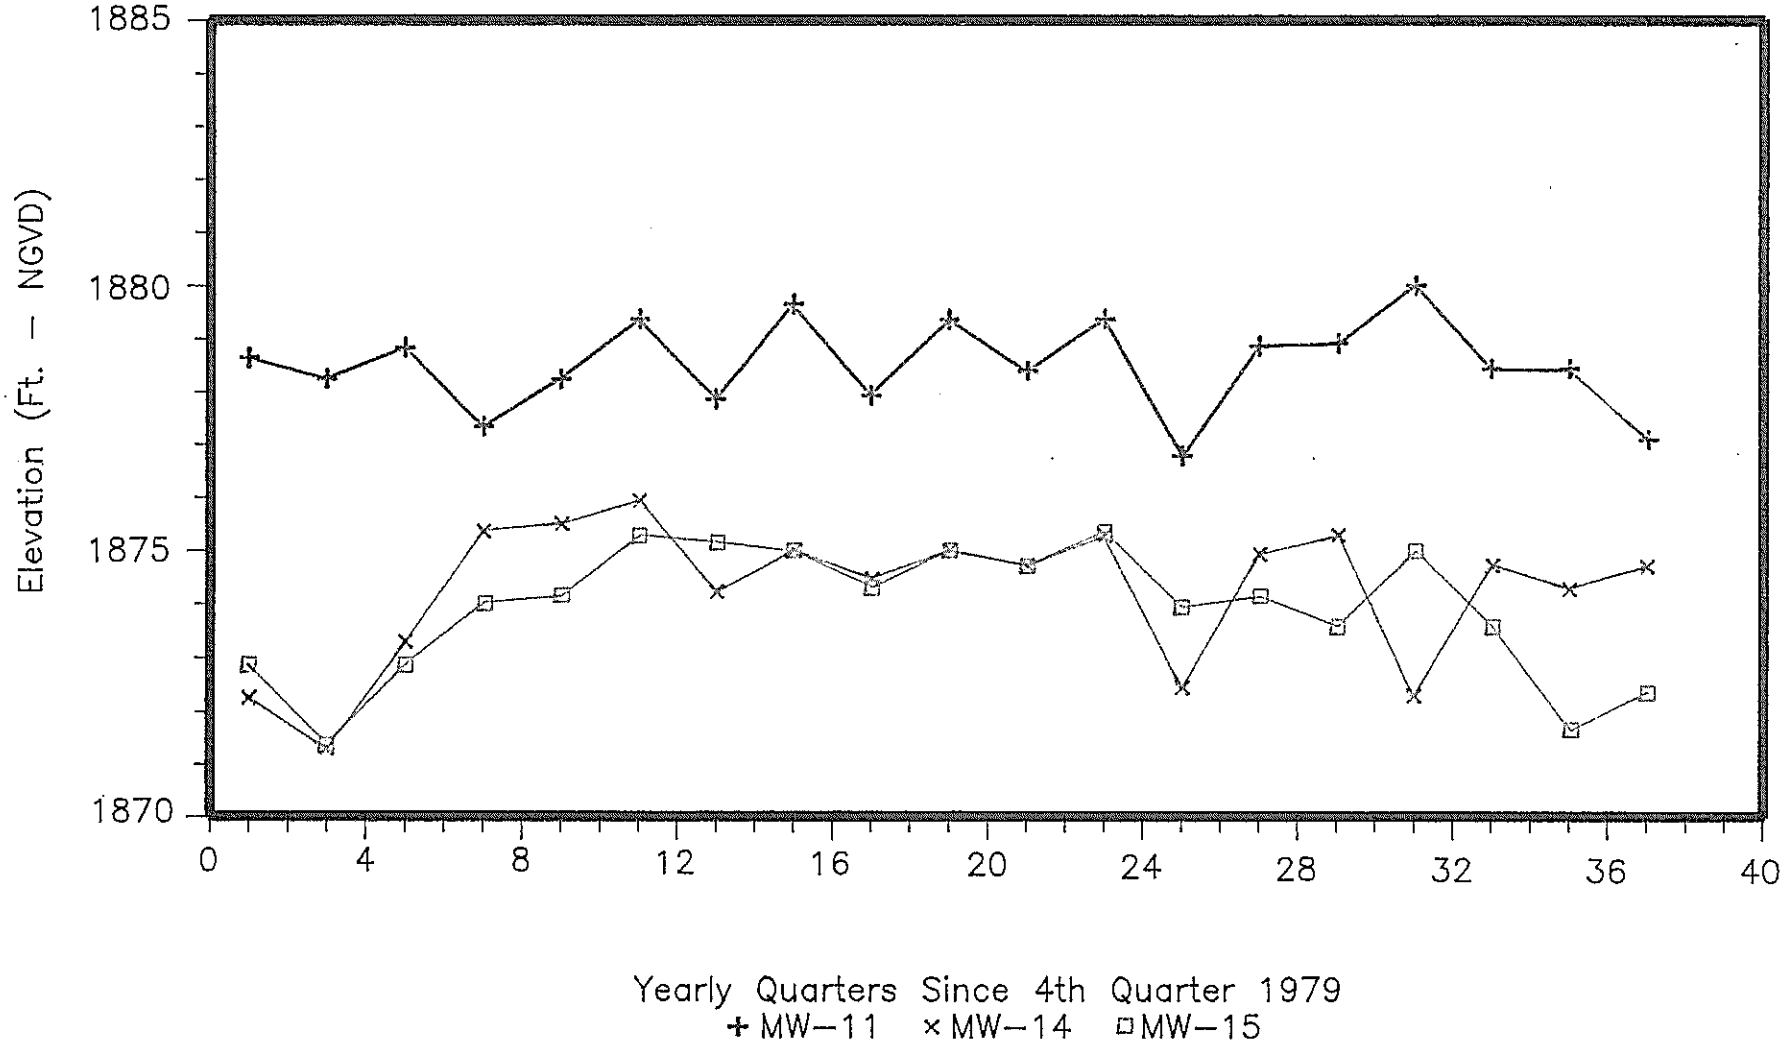
The Missouri River is located six miles south of the CCS ash disposal ponds. Flow direction is altered locally by mining and waste disposal activities.



The groundwater flow pattern in the vicinity of CCS follows the wetland and legal drain system. The flow pattern passes through Weller Slough, Samuelson Slough, Saylor Slough, Gradin Slough and continues into the Coal Lake Coulee and/or the Buffalo Creek drainage systems.

As stated above, local influences can modify the regional groundwater flow pattern. A localized influence can be seen on Figure 15 near the EAP, probably associated with the northwest quadrant of the EAP.

The hydrograph shown in Figure 17 shows that the water level in the upland well (MW 6) has a higher elevation than the lowland well (MW 11), as expected. The hydrograph also shows a good correlation in the fluctuation data of the two wells. This indicates that the two wells, and the two aquifers, act as a connected hydrological system. Groundwater levels in the aquifers have generally remained the same during the nine years of plant operation, with the exception of normal seasonal variations, within a range of about four feet.



However, water level fluctuations in monitoring wells near constructed ponds are influenced by the ponds. Figure 18 is a hydrograph for MW 11, MW 14 and MW 15. MW 14 is located north of the EAP in an area that is impacted by water level fluctuations in the SAP and EAP. MW 15 is located east of the EAP where it has been locally influenced by loading in the EAP and generally influenced by site wide water level changes. See Figure 19 for monitoring well locations.

Fluctuations in the water level which do not correlate with the regional pattern can be explained by comparison with pond usage, as summarized in Table 7. The hydrograph for MW 11 is provided as a "normal" groundwater fluctuation pattern. Pond induced impacts to groundwater monitoring wells include a lag between the pond activity and a correlative response in the groundwater system at the well.

MW 14 shows a significant water level increase when SAP loading began. Water levels partially decreased when the SAP was taken out of service and the EAP operation began. MW 14 has continued to show elevated water levels with some fluctuations as cycled use of the ponds has taken place. MW 15 had shown a general increase of water levels since plant operation began and it has continued as a part of site wide water level impacts. Water level at MW 14 has decreased along with the regional ground water level in relation to recent drought conditions.

C. Groundwater Quality

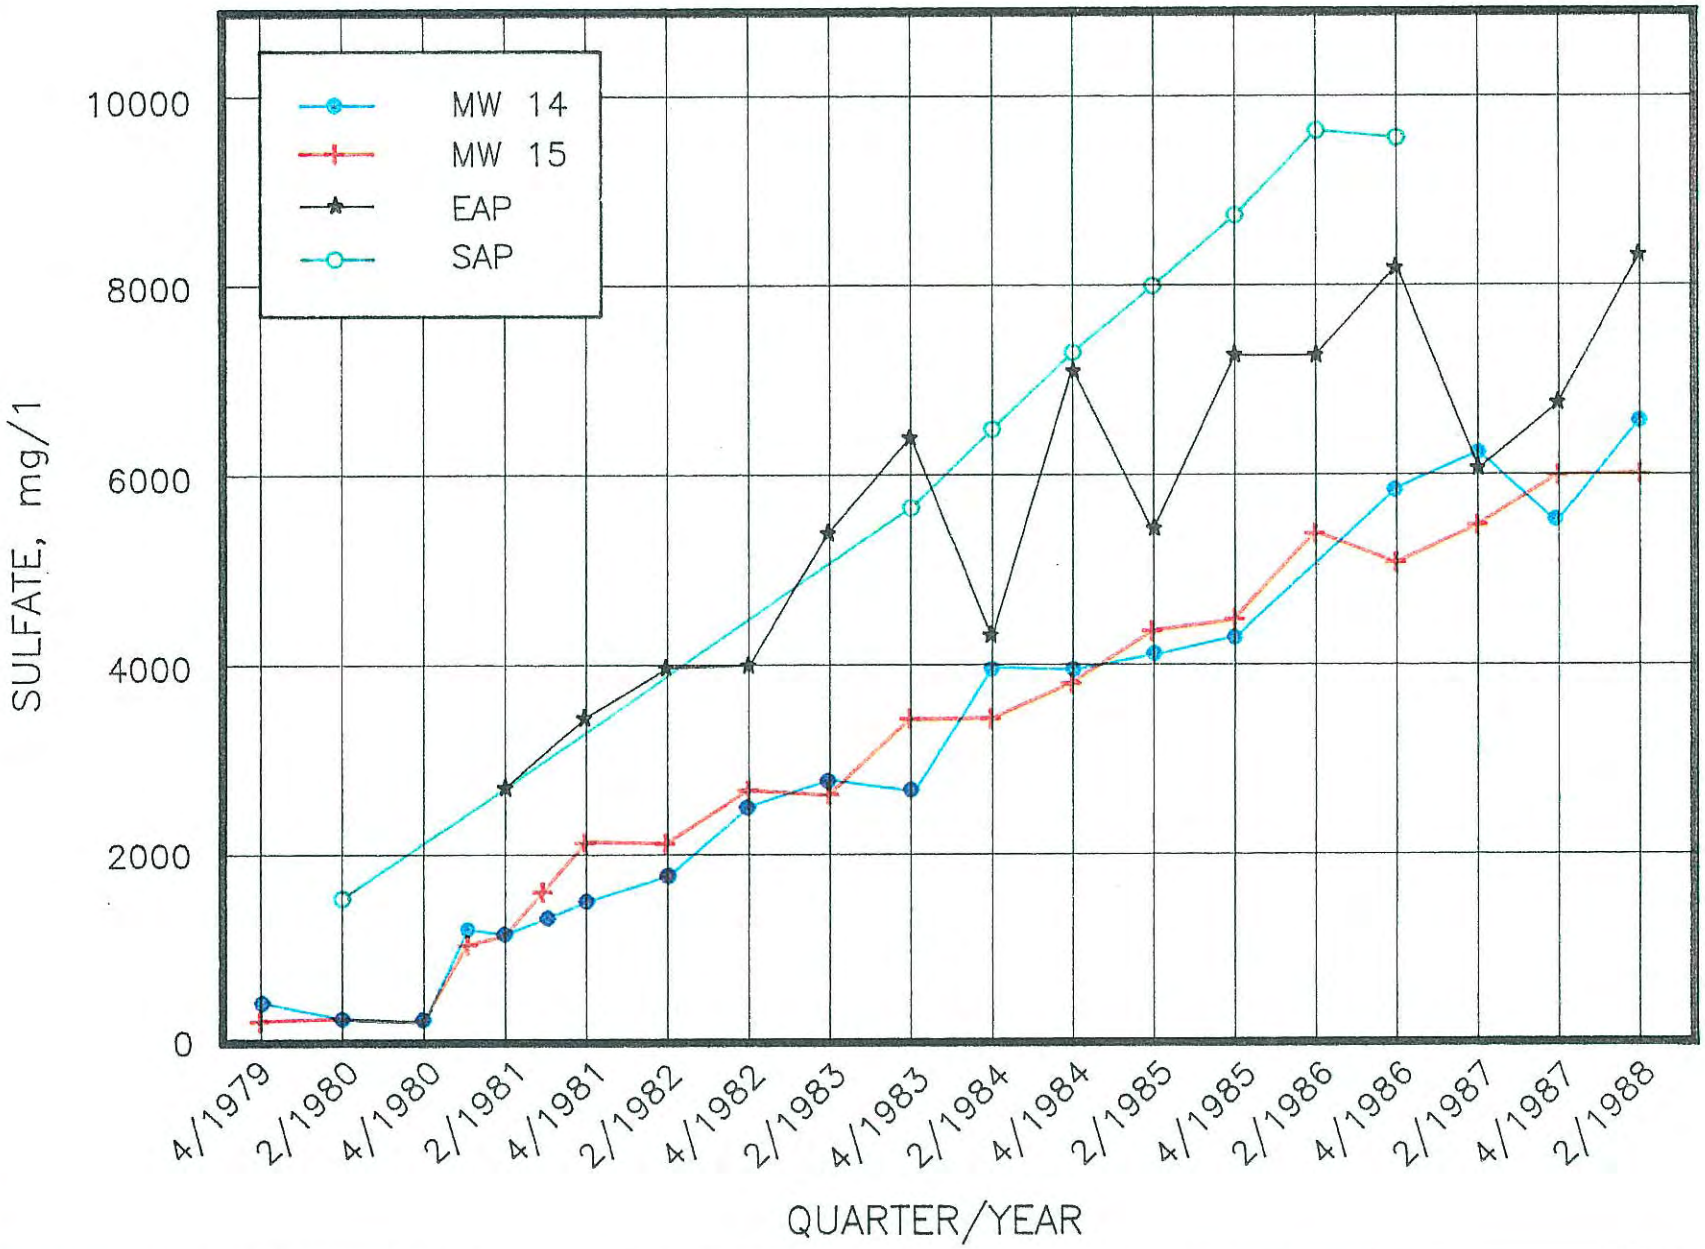
A network of groundwater monitoring wells has been in existence at the CCS site since 1979, with sampling and analysis generally occurring twice a year. This monitoring program has documented significant sulfate contamination, and to a lesser extent, boron contamination, in the upper level aquifer in the vicinity of the EAP and SAP. Metals present in the ash and sludge appear to get tied up chemically and have not been found in significant quantities outside of the impoundments. (For more discussion of the chemistry of the sludge and ash, see Section I.) While there are not enough monitoring well locations to distinguish

TABLE 7

Pond Usage Summary
Coal Creek Station

Date	Activity
Spring 1979	- CCS Unit 1 commenced operations. - South Ash Pond was placed in service.
Summer 1979	- Excessive seepage was observed from the South Ash Pond.
July 1980	- East Ash Pond was placed in service.
Summer 1981	- South Ash Pond was repaired.
Spring 1982	- South Ash Pond was returned to service.
Summer 1987	- South Ash Pond was taken out of service. - West portion of the East Ash Pond was placed in service.
Fall 1988	- West portion of the East Ash Pond was taken out of service. - West portion of the South Ash Pond was placed in service.

between the effects of the EAP and the SAP, other evidence, especially site geology, is indicative of the EAP's major role in this contamination. It is this contamination that has led to the design and operational modifications proposed in this application.



Data from the groundwater monitoring program is reported to the Department annually and therefore is not included in this application; however, several trend charts are provided as a summary of the data and to illustrate the conditions of the groundwater in the vicinity of the EAP.

Generally, sulfate is the parameter that is most directly associated with excess pond seepage. Water quality trend chart 1 (Chart 1) shows an historical picture of sulfate concentrations in both the EAP and the SAP, as well as in the two shallow wells located near the EAP. There is a distinct correlation between the EAP and SAP, and the groundwater, with a steady upward trend in the sulfate concentrations, now at a level in the range of 6,000 to 7,000 mg/l, in the groundwater. This compares to 1979 sulfate levels in the groundwater of less than 500 mg/l.

Boron trends at the same locations are shown on Chart 2. Basically, it's the same trend as with sulfate; however, the concentrations are a couple of orders of magnitude less. Chart 3 shows arsenic concentrations, again for the same locations. The results here show that arsenic gets tied up chemically before reaching the shallow aquifer adjacent to the impoundments. Historical data is available for the complete parameter list at the Department. The parameter list is shown as Table 8.

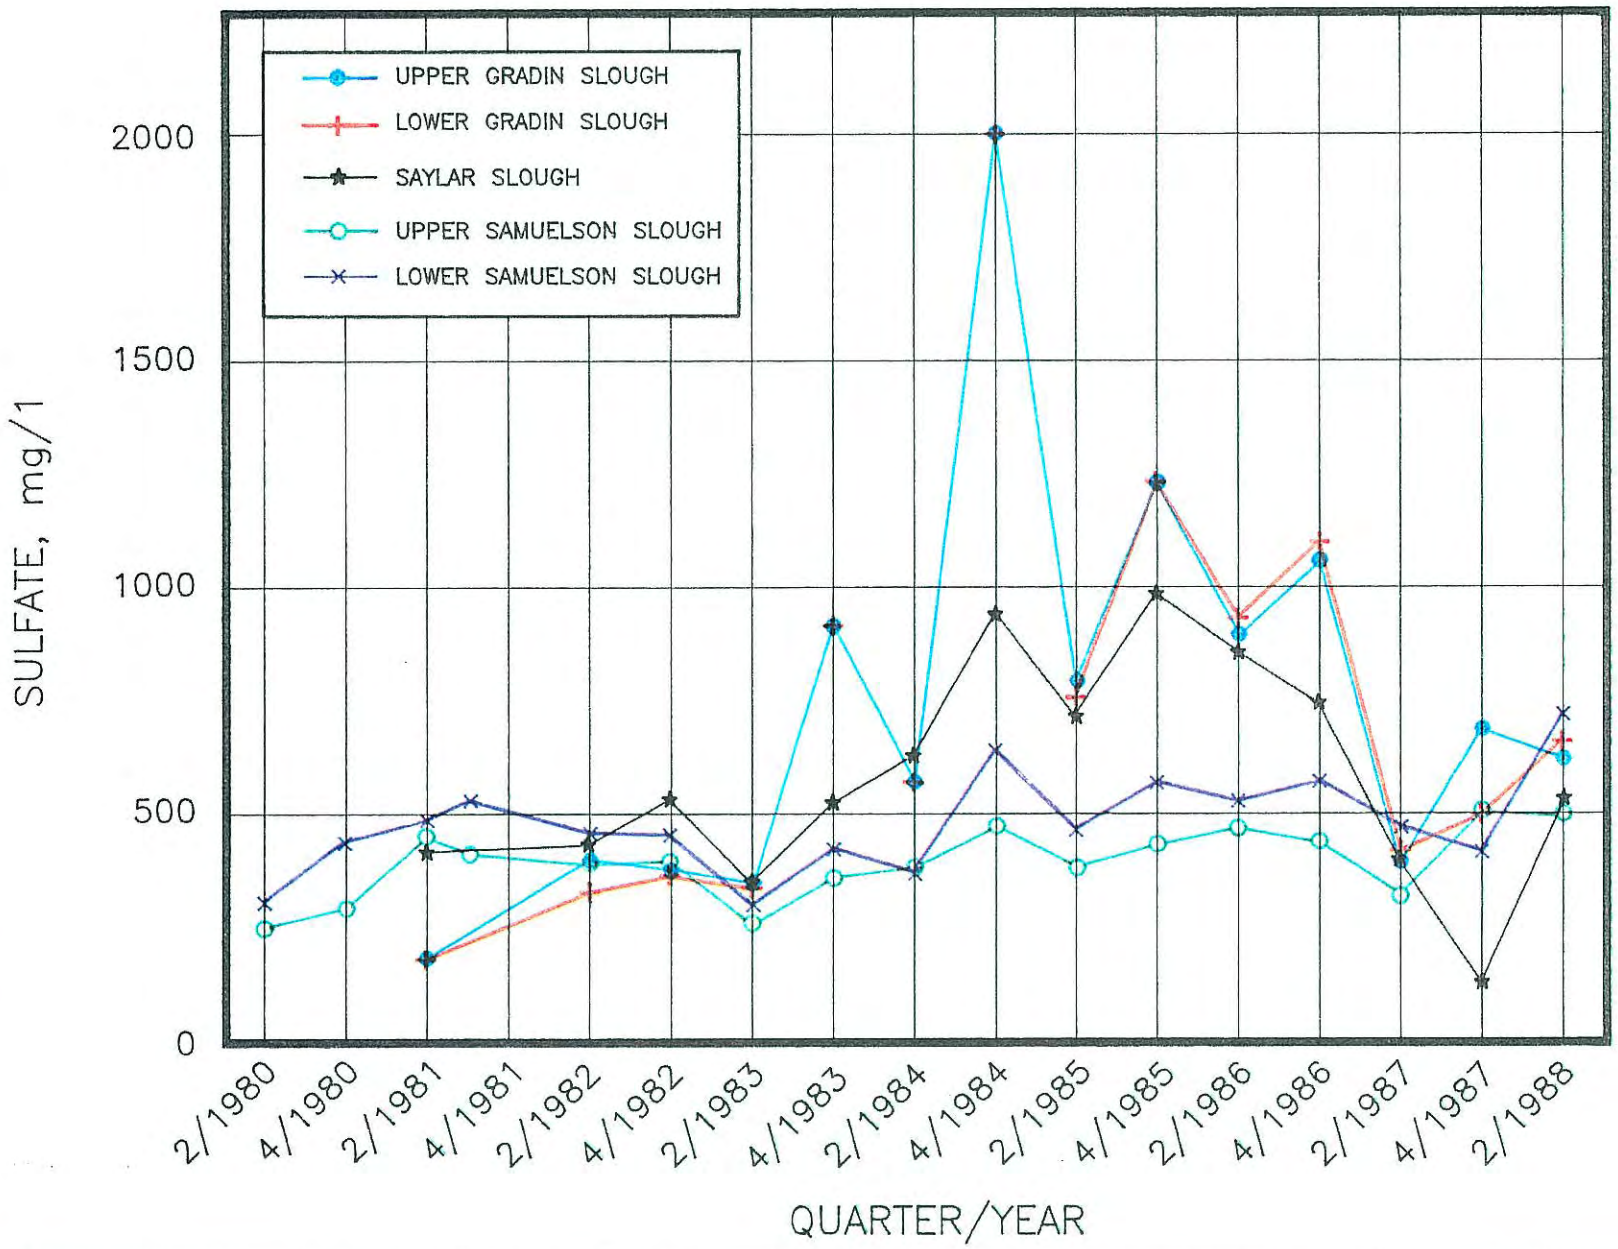
* Indicates parameters analyzed for at each sampling period, all locations. All other parameters are done periodically or only at selected locations.



Using sulfate as an indicator, Chart 4 shows that the deep wells in the vicinity of the EAP, MW 9 (screened interval 43 to 53 feet below the surface) and MW 13 (screened interval 45 to 55 feet below the surface), have remained mostly unaffected by the wet impoundments, with a slight perturbation in the early 1980's when the EAP was in service. This is consistent with vertical gradients developed by Foth & Van Dyke which show the EAP area to be mainly a groundwater to surface water discharge area with some influence from the impoundments.

D. Surface Water Quality

Surface water in the vicinity of the EAP is connected hydrologically to the shallow aquifer and thus is affected by contamination of the shallow aquifer. Chart 5 shows historical data for the parameter sulfate, for five sampling locations at three local wetlands. The upward trend in the early 1980's likely shows influence from the EAP and SAP. The trend reverses, however, toward the end of the period, indicative of management practices aimed at minimizing the amount of seepage. These practices included relining the SAP and taking the EAP out of service; and when it was necessary to place the EAP back in service, partitioning it so that only about a half of the impoundment was actually used.

Water Quality Trend Chart 5

Cooperative Power

V. CONSTRUCTION PLANS AND SPECIFICATIONS

A. Overview

The major design consideration that went into this project was to achieve the minimization or elimination of leachate flowing into the groundwater table. This is to be accomplished in the following ways for all parts of the EAP except the southwest section. The wastes already in the southwestern section of the EAP will be dewatered and subjected to specifications 3-5 below.

1. Elevating the bottom of the disposal area to a minimum of five feet above the water table.

2. Placing five feet of clay on the bottom with a permeability of less than 1×10^{-7} cm/sec.

3. Controlling runoff.

4. Sloping and capping the facility to eliminate infiltration, and thus, any medium for groundwater contamination.

5. Maintaining the closed facility to prevent erosion of the cap.

Not only will the above design considerations minimize leachate that reaches the groundwater table, they will also allow for significant long-term improvement in local groundwater quality.

B. Existing Conditions

A set of construction plans are included with this application. Drawing A-2 shows the existing contours of the EAP area. A partitioning dike separates the EAP roughly into two halves. The west portion of the EAP has recently been taken out of service and is partially full of ash and sludge. Water in the western part has been pumped to other impoundments in order to reduce the hydraulic head and attendant seepage through the bottom of that part of the EAP.

Approximately one-half of the way up the partitioning dike is another, shallower dike which runs across the "neck" of the western portion of the EAP. It is indicated as a "berm" on Drawing A-2. The purpose of this dike was to contain the solids in the southern part of that half of the impoundment and to allow excess water to flow to a pumping station located at the northern end of the impoundment. Thus, most of the solids in the western portion of the EAP are in the southern reaches.

The eastern portion of the EAP has been out of service since 1982. Water that has accumulated in this part of the EAP is periodically pumped to other impoundments.

C. Construction Plans

The proposed design for the EAP calls for the staged development of six waste disposal cells in the EAP. See Drawing A-3 for the sequence of cells proposed for filling the disposal area.

As stated above, the Sequence No. 1 area (southwest corner) is already partially filled. Because the geology in the Sequence No. 1 area is favorable, and because the cost of moving and disposing of this substantial volume of material is very high, estimated to be about $10 million, it is proposed that those materials remain in the EAP. In other words, it is neither practical nor necessary to remove those wastes. However, the wastes in place will be thoroughly dewatered and capped to control runoff and infiltration.

Foth and Van Dyke has estimated the pond bottom to be two feet or less above current groundwater table in the southwest section of the EAP. It is predicted, however, that the water table will drop now that the EAP is out of service and dewatered. This should provide some thickness of unsaturated soil between the water table and the disposed wastes. With a properly sloped final cap of impervious materials, there should be no infiltration or medium for further contamination of groundwater.

Construction to prepare the EAP to receive wastes would begin in the northwest section, where any ash materials will be removed to the Filling Sequence No. 1. area and 12 inches of suitable materials be placed over the wastes and compacted to allow drainage in a northeasterly direction as shown in Drawing A-4.

Additional site construction is required to prepare the EAP to accept wastes. The EAP bottom, exclusive of the southwest corner, will be shaped prior to placement of a clay liner to allow drainage in both a northeasterly and southeasterly direction as shown on Drawing A-4.

Placement of the clay liner will be to the approximate elevations shown on Drawing A-5. Details of the construction of the clay liner and side slopes are shown on Drawing A-3.

The clay material to be placed should be tested to ensure it meets the desired gradation, plasticity and permeability as shown in Table 9. This clay should be compacted to achieve a degree of compaction of 95 percent of Standard Proctor. The maximum thickness of a compacted lift should not exceed eight inches.

The following clay source testing program is planned to determine source suitability for clay soils meeting the specifications of Table 9.

- Grain size distribution to the .002 millimeter particle size and Atterberg limit testing on samples collected at a rate of one sample for each 10,000 cubic yards of proposed in-place clay.

- Moisture density curves using the 95 percent of Standard Proctor method on samples collected at a rate of one sample for each 20,000 cubic yards of proposed in-place clay.

- One test evaluating the relationship between compaction and hydraulic conductivity shall be developed for each borrow source. This shall be accomplished by testing the sample corresponding to each point established on the Proctor curve for hydraulic conductivity.

Sidewall clay placement should also follow the specifications listed in Table 9.

The clay liner sidewall shall be constructed to a minimum thickness of two feet measured perpendicular to the liner.

Clay liner sidewalls shall be constructed by placing clay in compacted lifts of one foot maximum thickness. The completed liner soils shall have a maximum coefficient of permeability of 1×10^{-7} cm/sec.

Sufficient testing shall be completed on representative clay samples prior to construction to verify the performance of the clay liner based on proposed construction specifications and techniques.

During construction, a quality control program shall be implemented to ensure that the clay liner will function as designed. Table 10 outlines a recommended quality control program for clay liner placement along the side slopes. This program shall be used as a minimum guide in selecting a project quality control program. At a minimum, the final quality control program selected shall be based on the quality of the clay, clay test performance, construction equipment, and construction techniques.

Quality control testing during placement of clay soils on the base of the disposal area should follow the program presented in Table 10, with two exceptions: 1) density tests should be performed on a 200-foot grid pattern on each eight-inch layer of compacted clay soil, and 2) undisturbed laboratory permeability tests should be performed at a frequency of one-per-two-acres per eight-inch compacted lift.

TABLE 9

Clay Soil Specification

Liquid limit	>/= 30
Plasticity index	>/= 15
P200 content	>/= 50%
Clay size fraction	>/= 25%
Compaction	>/= 95% Standard Proctor density
Permeability	</= 1 x 10^{-7} cm/sec

Clay soil shall be free from organic material, boulders, cobbles, excessive amounts of gravel (greater than 3/4") and other deleterious substances.

The total volume of clay necessary for the base lining and the sidewalls of the disposal area is estimated at 1,615,000 cubic yards.

Estimated quantities of clay necessary for the base lining and sidewalls of the individual programmed disposal sequences are:

Sequence No. 2	565,000 cubic yards
Sequence No. 4	702,000 cubic yards
Sequence No. 6	348,000 cubic yards

The above volumes of clay include a 30 percent shrinkage factor.

TABLE 10

Recommended Clay Sidewall Placement Quality Control Program

Test	Frequency
Density	1 per 100 lineal feet of clay sidewall per 12-inch compacted lift
Standard Proctor	1 per each distinct clay type (1 per 20,000 cubic yards minimum)
Atterberg Limits	1 per 10,000 cubic yards
Grain Size	1 per 10,000 cubic yards
Undisturbed Permeability	1 per 500 lineal feet per 10 feet of clay sidewall placement measured vertically

Additional testing shall be completed as needed to assure quality construction.

VI. GROUNDWATER MONITORING

A groundwater monitoring program has been in place at this site since 1979. Several new groundwater wells were added to the monitoring network in 1986 to get more data from the area east, and downstream, of the EAP. As a part of an examination of the hydrology in the vicinity of the SAP, more monitoring wells, still, were added in 1988, this time surrounding the SAP. Figure 19 shows the locations of the wells in the vicinity of the impoundments. Parameters and frequency of sampling have already been established by the Department. The groundwater monitoring program should document steadily improving quality of the local groundwater.

VII. OPERATION AND MANAGEMENT METHODS

A. Site Sequencing

A proposed phasing sequence of the disposal area is illustrated on Drawing Nos. A-6 through A-11. Six filling sequences will be used to provide for a systematic filling sequence; No. 1 from the southwest side of the southwest section of the EAP to the northeast, and No. 2 from the southwest side of the EAP to the north. The third sequence will be over portions of the first two phases as illustrated on Drawing No. A-8. The remaining disposal sequences will be as diagramed on Drawing No. A-3.

The filling sequences are designed to bring portions of the disposal area to final grade as soon as possible. The sequencing also routes surface water drainage away from the working area as described in the next section. The drainage of Sequence Nos. 1 and 2 areas is routed to the northeast corner of the respective disposal cells to allow for removal by pumping as required.

Any contact water will be collected and periodically pumped to the east evaporation pond or south ash pond.

Approximately 22,821,000 cubic yards of air space is available in the EAP disposal area. Filling Sequences Nos. 1, 2 and 3 contain 1,543,000 cubic yards, 3,651,400 cubic yards and 1,114,000 cubic yards of capacity, respectively.

Subsequent sequences available air space are estimated at:

Sequence No. 4	4,383,000 cubic yards
Sequence No. 5	4,151,000 cubic yards
Sequence No. 6	7,979,000 cubic yards

B. Site Filling

Site filling will progress in phases as shown on the drawings and as described in the previous section. The filling of each phase shall consist of a series of lifts. Each lift will be approximately ten feet thick to provide increased compaction. Each lift in the Sequence No. 1 operation shall be sloped to the northeast to route surface water drainage away from the active fill area. Subsequent sequences will route surface water drainage away from active fill areas as shown on Drawing No. A-5.

Access to the fill area for disposal will be provided by access roads entering the disposal area from both the north and the south. The road shall be routed over the compacted fill to the active fill area. The road shall be extended vertically as ash disposal progresses in order to provide ingress and egress for the duration of site filling. Access road grades shall not exceed 10 percent. The access road shall be maintained to provide access to the active fill area during all weather conditions. Access road construction shall consist of materials to provide easy maneuverability of vehicles. The road materials will reduce windblown dust during dry weather conditions and excessive rutting during wet weather conditions.

VIII. RECORD OF SOLID WASTE DISPOSAL ACTIVITY WITH THE COUNTY REGISTER OF DEEDS

A notarized affidavit specifying that this solid waste disposal site is permitted to accept solid wastes for disposal will be filed with the County Registrar of Deeds once the Department issues the permit. Said affidavit shall specify that another affidavit will be filed with the County Registrar of Deeds once the disposal operation is completed and the site is closed. The second affidavit will specify the types of wastes disposed at the facility and other pertinent details. The Department shall be provided with copies of these affidavits.

IX. SITE CLOSURE

A. Short Term Care

Final site grades are shown on Drawing A-11. A 12 percent maximum final slope is proposed, based on previous slope stability experience with ash disposal and discussions with the Department.

As each phase reaches capacity, the final cover shall be constructed on those slopes which reach cover elevations. The function of the final cover is to limit infiltration, route surface water off the disposal area and provide sufficient soil cover for vegetative growth. The final cover will consist of two feet of compacted clay, six feet of spoils material compacted to 90 percent Standard Proctor, 1.5 feet of subsoil, and six inches of topsoil. A detail of the final cover construction is included on Drawing A-3.

An interim cover of six-inch minimum thickness will be placed on those fill slopes that will be regraded during subsequent filling sequences.

Construction of the two-foot-thick clay layer of final cover shall be completed in accordance with specifications outlined in Table 11. Clay for the final cover shall be placed in compacted lifts of eight-inch maximum thickness.

The spoils material, subsoil and topsoil provide frost protection for the clay layer. The soils also provide a medium for vegetative growth.

TABLE 11

Recommended Clay Cover Placement Quality Control Program

Test	Frequency
Density	200-foot grid pattern per 8-inch compacted lift
Standard Proctor	A minimum of 1-per-10,000 cubic yards and 1 each for each major soil type utilized
Atterberg limits	400-foot grid pattern per 8-inch lift
Grain Size	400-foot grid pattern per lift
Undisturbed Permeability	1-per-5-acres per 8-inch lift

All final cover areas and adjacent areas disturbed by construction shall be topsoiled, seeded, fertilized and mulched. Topsoil shall be analyzed to obtain appropriate fertilizer recommendations. Fertilizer, seed, and mulch shall be applied as recommended to provide vegetative cover compatible with regional vegetation.

Table 12 presents final cover construction quantities. At the completion of closure activities, permanent fencing shall be placed around the disposal perimeter. The purpose of the fencing is to limit site access to maintenance and inspection vehicles only. The fencing shall be adequate to prohibit livestock and any unauthorized vehicles from entering the disposal area. A locking gate or gates shall be installed to provide access for maintenance and inspection vehicles.

B. Long Term Care

Following site closure, the disposal area will be inspected at least twice a year for five years.

During each inspection the following items shall be observed.

1. Soil cover. Topsoil, subsoil, and clay cover soils shall be inspected for erosion, differential settlement, vegetation stability and any indication of vegetative stress.

2. Drainage control facilities. Drainage swales shall be inspected for erosion or blockage.

TABLE 12

Estimated Soil Quantities for Final Cover Construction

Total Site

Construction Item	Quantity
2 ft. clay layer*	886,600 cubic yards
6 ft. spoils layer	2,127,000 cubic yards
1.5 ft. subsoil layer	532,000 cubic yards
6 in. topsoil layer	178,000 cubic yards

Estimated Soil Quantities by Sequence Areas

Construction Item	Sequence No. 1	2	3	4	5	6
2 ft. clay layer (cubic yards)*	104,000	89,700	58,500	166,400	304,200	163,800
6 ft. spoils layer (cubic yards)	248,000	226,000	135,000	416,000	704,000	398,000
1.5 ft. subsoil layer (cubic yards)	62,000	56,500	34,000	104,000	176,000	99,500
6 inches topsoil layer (cubic yards)	21,000	19,000	11,000	35,000	59,000	33,000

*Clay volume includes a 30 percent shrinkage factor

3. Land surface care. Surface maintenance after closure includes maintaining proper cover soil and vegetation on the site, and the inspection and repair of surface water control structures and monitoring devices.

4. Runoff control. Surface water drainage swales which control surface water runoff should be inspected for erosion and blockage and maintained as needed.

5. Erosion care. Rapidly growing grasses are to be planted on the closed landfill to minimize erosion. Erosion damage to vegetated cover soils could occur due to differential settlement or severe weather conditions. Eroded soils and/or damaged vegetative cover will be replaced if necessary.

6. Settlement. Differential settlement may occur in closed areas, requiring some maintenance. Areas shall be inspected semi-annually for locations that have settled, causing surface water to pond or erosion to occur. These locations are to be regraded and reseeded as soon as possible.

INTRODUCTION

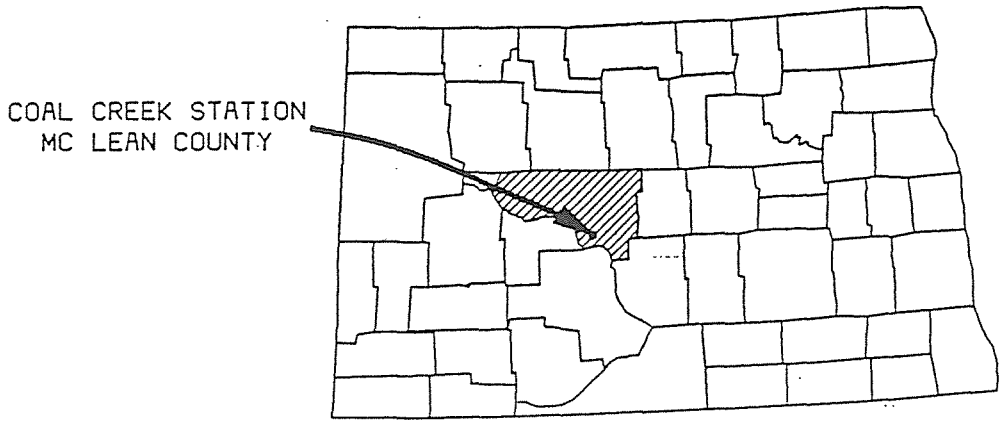
This evaluation of 1993 water quality data for Coal Creek Station (CCS) was prepared in accordance with conditions outlined in CCS special waste disposal permits SU-033, SU-091, SU-095, and SU-118.

Objectives of the report are to:

- Present groundwater and surface water data collected at CCS during 1993.
- Discuss short-term and long-term water quality trends at CCS.
- Provide a statistical analysis of the water quality data in accordance with the 1993 North Dakota State Department of Health (NDSDH) "Guidelines for Statistical Analysis of Ground Water Monitoring Data from Solid Waste Facilities".

The text portion of the report includes a review of water quality data collected during the reporting period, a brief summary of the statistical analyses conducted on the data, results of the analyses, and a discussion of the significance of the results in relation to water quality guidelines.

In previous years, the text included a site overview that described the activity and status of each special use site. For the 1993 reporting period, this information was submitted under separate cover as an annual report for solid waste management facilities as required by NDAC 33-20-04.1-04.3 (see Appendix A).



SITE BACKGROUND

Coal Creek Station is a coal-fired power plant near Underwood, North Dakota (Figure 1) that produces ash as a byproduct of the combustion process. The ash is a solid waste that typically has been placed in several storage ponds at the facility. A ground water monitoring network (Figure 2, Appendix B) has been in-place, and periodically upgraded, since the plant began operation in 1979. At one point the monitoring network at CCS and at the adjacent Falkirk Mine solid waste facilities included 158 ground water monitoring wells and 27 surface water monitoring locations.

Annual water quality monitoring reports have been formally submitted to the NDSDH since 1989. These reports have included plots of selected data that were visually analyzed for trends. In late 1991/early 1992, a comprehensive evaluation of the water quality monitoring program was undertaken. CP believed a more streamlined program was warranted with the impending completion of the pond lining project and that such a program could track representative and significant data.

The revised program, approved by NDSDH in March 1992, includes 65 reportable monitoring locations and 6 reportable lab parameters (from 47 lab parameters previously). Six water quality parameters (arsenic, boron, chloride, selenium, strontium, and sulfate) associated with ash were recognized in the 1991/1992 data evaluation as being potentially significant and representative of water quality changes. Although there are no regulatory requirements associated with groundwater or surface water monitoring at CCS, the data are compared to the following standards :

Parameter	Standard	Source
Arsenic	0.05 mg/l	SDWA Primary Drinking Water Standard
Boron	0.75 mg/l	North Dakota Class I Stream Standard
Chloride	250 mg/l	SDWA Secondary Drinking Water Standard
Selenium	0.01 mg/l	SDWA Primary Drinking Water Standard
Strontium	0.05 mg/l	Arsenic Standard
Sulfate	250 mg/l	SDWA Secondary Drinking Water Standard

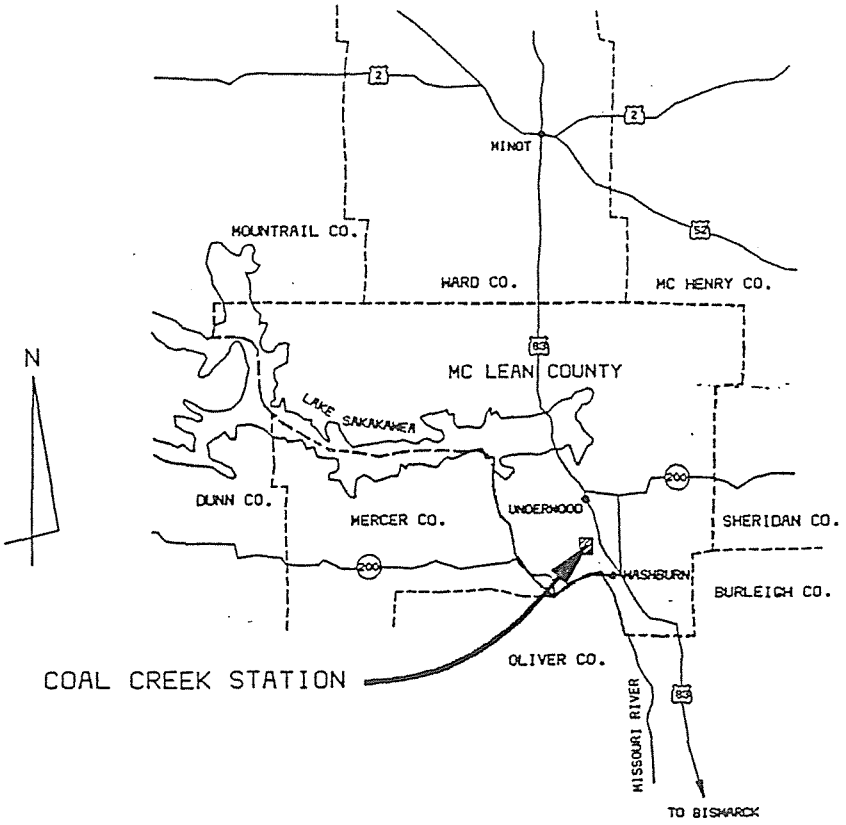


FIGURE 1. Site Location Map

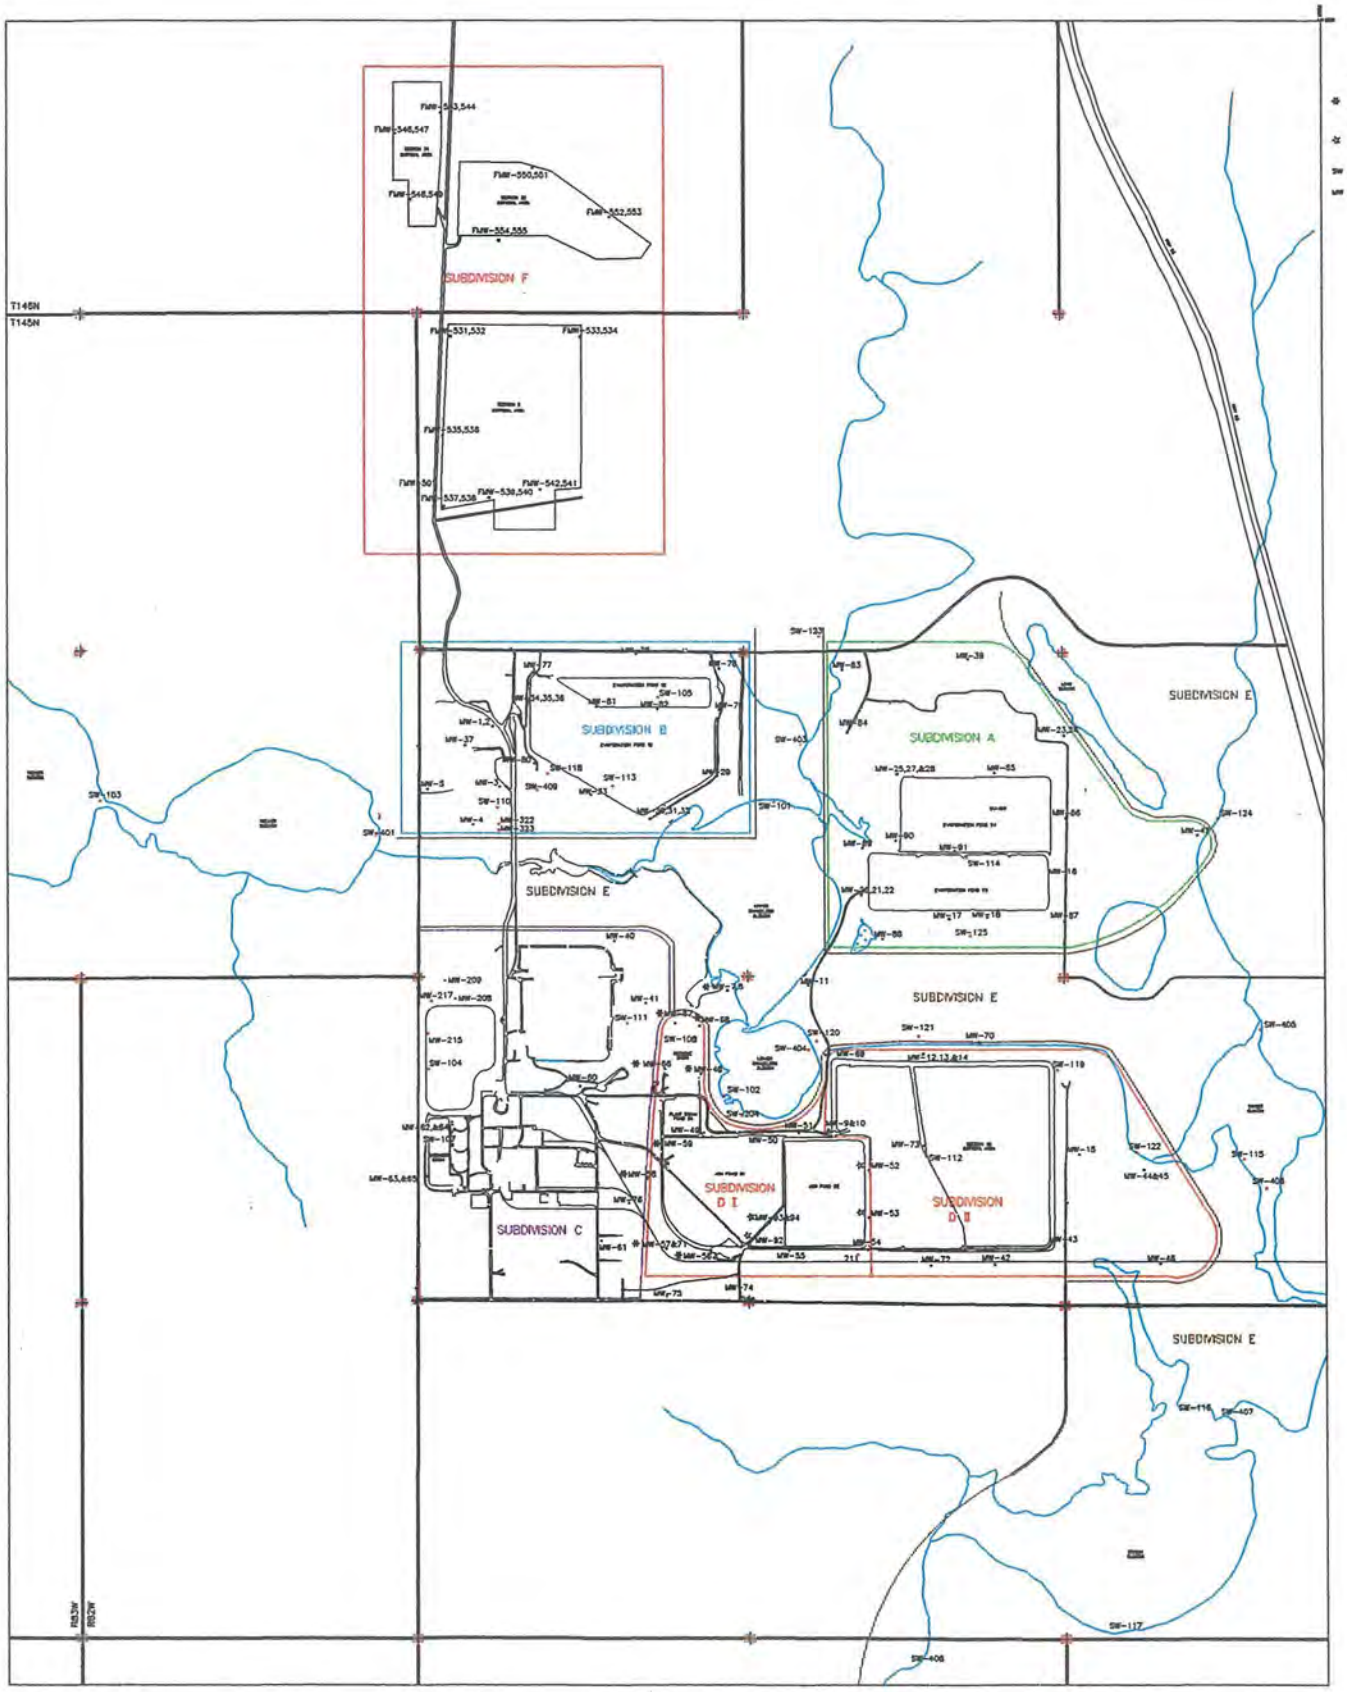

FIGURE 2. Water Quality Monitoring Locations and Subdivisions

These are referred to throughout this report as water quality guidelines, but are for comparative purposes only.

Additional data (field parameters, laboratory parameters, and water levels) are collected for internal use. The statistical evaluation reported in this document has been conducted using the modified monitoring locations and the six parameters listed above. A summary of the 1993 water quality monitoring program is provided in Appendix C.

Water quality trends at CCS have been influenced by operational activities such as variable pond usage and repairs to the ponds. A summary of pond usage at the site is provided as Table 1. Water quality data at the adjacent Falkirk Mine have been influenced by mining and subsequent development of engineered landfills.

METHODS

Water quality data collected at CCS are generally divided into seven areas or "subdivisions" (Figure 2), and for each subdivision, this report:

- Discusses how historical monitoring data and other information were used to select a statistical method;
- Discusses the assumptions used in selecting and evaluating the statistical tests;
- Describes the methods and explains formulas, calculations, or tables used;
- Discusses error rates, where applicable; and
- Explains the implications of the statistical test results.

The water quality analysis for 1993 is confined to the six reportable parameters: arsenic, boron, chloride, selenium, strontium, and sulfate. Arsenic is addressed separately because it behaves similarly in all subdivisions. In 1993, arsenic was not detected above the water quality guideline of 0.05 mg/l at any of the monitoring locations. Selenium was only detected above the water quality guideline of 0.01 mg/l at a total of eight monitoring locations (three of which were marginal exceedances), and is only discussed in those subdivisions where the exceedances occurred.

Throughout the statistical analysis portion of this report the word "significant" is used extensively. In this context, the meaning of "significant" is with regard to the results of a statistical test being "statistically significant". The results of a statistical test can be "significant", even though the values being examined are not above established water quality guidelines.

Statistical analysis of water quality data provides an unbiased validation of previously reported trends using standard procedures. The analysis has been conducted in compliance with the new NDSDH requirements, including application of control chart and tolerance interval methods. A discussion of statistical methods used is provided in Appendix D.

Previous evaluations of the water quality data have shown that the CCS ash ponds and evaporation ponds have adversely affected local water quality (*Water Quality Trends, Coal Creek Station and Falkirk Mine Disposal Area*, Dames & Moore, November 1991). The extent and magnitude of the impacts were influenced by varied uses of the ponds and by operational needs. Based on these findings, extensive repairs have been completed to mitigate water quality conditions. Pond repairs began in 1987 and were completed in 1993. The influence of these repairs on apparent downgradient ground water quality is discussed throughout this report, where applicable.

Notes: I = In Service O = Out of Service D = Dewatering R = Repair

CCS water quality data have been plotted for reference and show that operational changes do affect water quality conditions. Water quality data for all monitoring locations examined in this report are provided in time trend plots for each subdivision. Additional trend plots, with associated statistical test results overlain on the plots, are provided in Appendix E. For all 1993 trend plots, average values were used if there was more than one data point in that year for a particular parameter.

DISCUSSION

SUBDIVISION A

This subdivision is located in the northeast section of the plant site (Figure 3) and encompasses portions along Long Slough, Evaporation Ponds #93 and #94, and the northeastern edge of Samuelson Slough. The water quality sampling locations (with completion depths below ground surface for monitoring wells) monitoring this subdivision and reported herein are as follows:

Ground Water

Upgradient	Downgradient	Additional
MW-23 (40 ft)	MW-17 (20 ft)	MW-16(23ft) Downgradient]
MW-24 (25 ft)	MW-18 (16 ft)	MW-20(31.5ft)[Downgradient]
MW-83 (19.5 ft)	MW-87 (10.5 ft)	MW-21 (19 ft) [Downgradient]
	MW-22 (10 ft)	MW-90 (9 ft) [Downgradient]
		MW-91(34.5 ft) [Downgradient]

Surface Water

SW-109
SW-114

A summary of the historical usage of Ponds #93 and #94 in this subdivision is provided in Table 1. Pond #93 was removed from service in December of 1991, lined during the summer of 1992 and placed back in service in November of 1992. Pond #94 was repaired in 1991 and has been in service since 1992.

Qualitative Discussion of Historical Water Quality Data

Time series data plots of the reportable parameter concentrations for the planned water quality monitoring locations in Subdivision A are provided in this section. Table 2 provides a summary of the most recent measured concentrations for Subdivision A in comparison to the water quality guidelines.

Most of the wells and reportable parameters have a period of record extending from 1980 to the present, although the records for wells MW-83 and MW-87 begin in 1989. The following sections provide qualitative descriptions of water quality in the subdivision, based on an examination of water quality trends for the various monitoring wells and knowledge of the historical usage of the evaporation ponds within this subdivision.

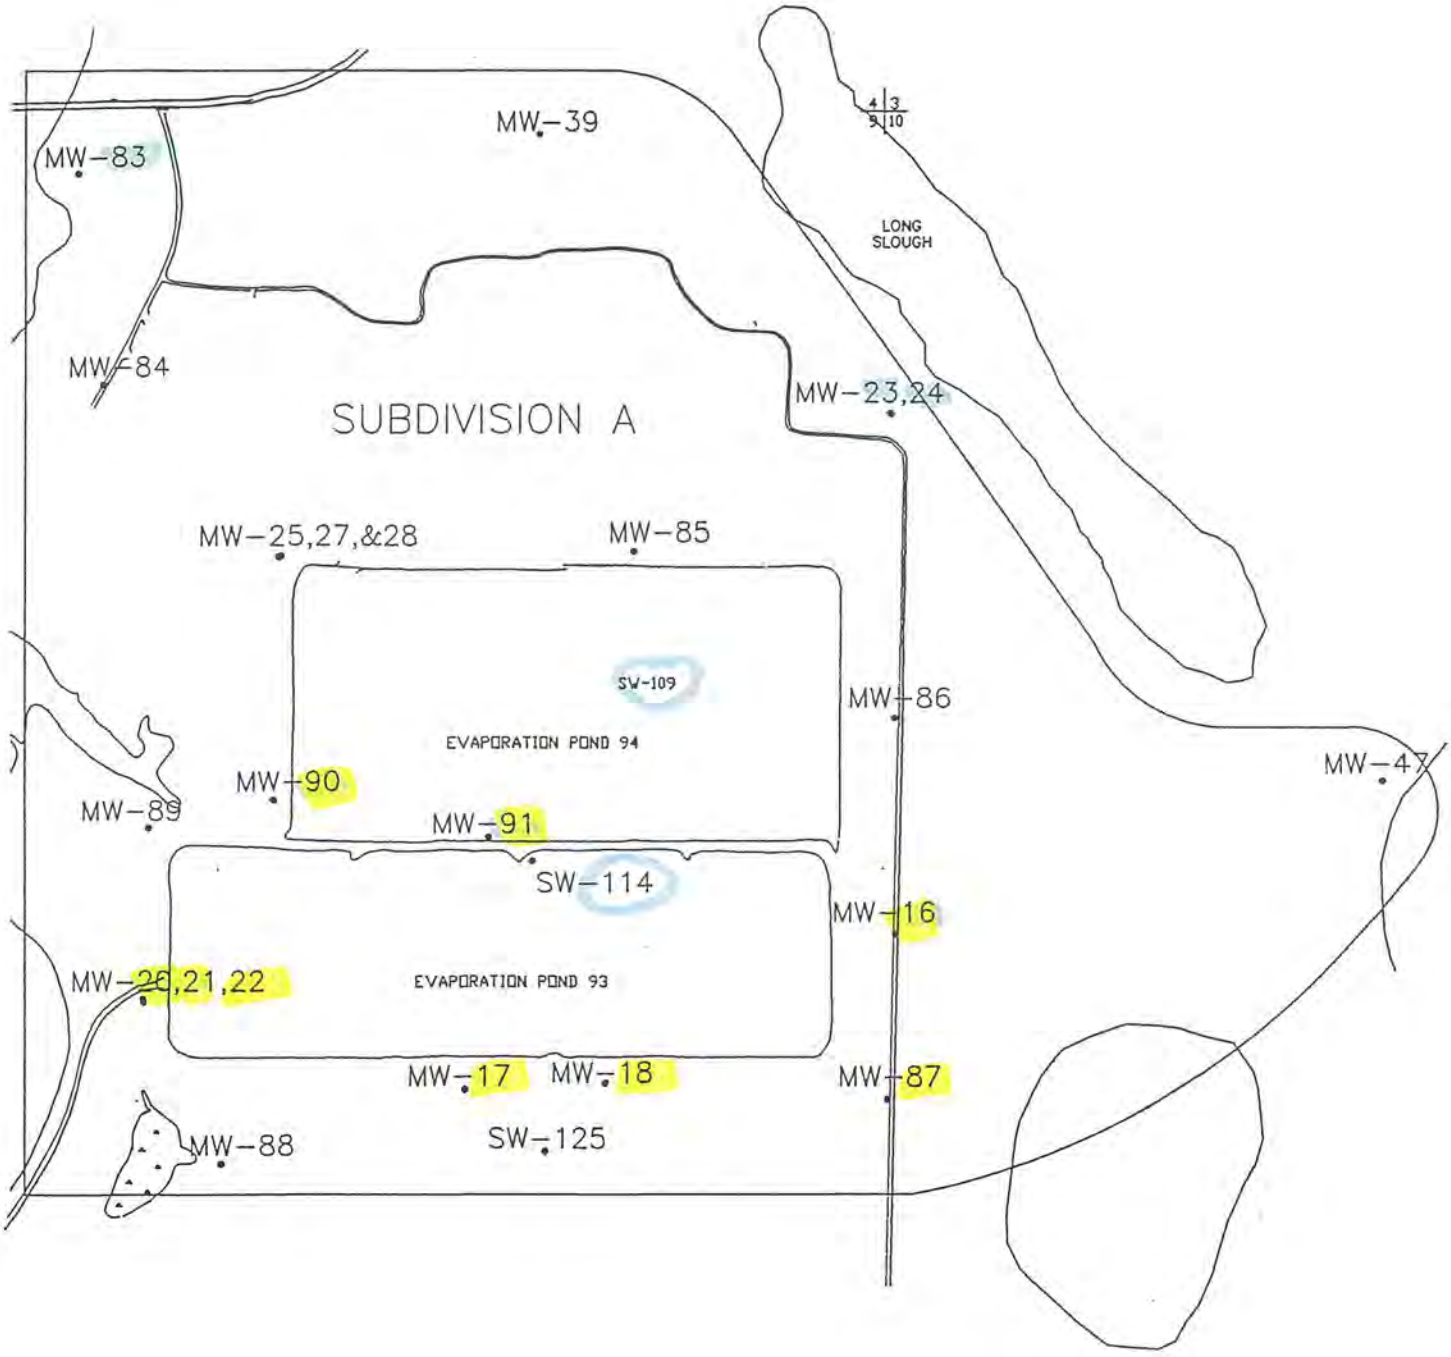

FIGURE 3. Subdivision A Water Quality Monitoring Locations

Notes: All concentrations are presented in units of milligrams per liter.
Shaded values indicate latest results which exceed the water quality guidelines.
NA = Not Analyzed
[1] WQ Guide = Water Quality Guideline

Upgradient Wells

Upgradient wells MW-23, MW-24 and MW-83 (Figures 4 and 5) document ambient conditions and show no obvious trends during the period of record, other than a slight increase in chloride concentrations at well MW-23 over time. Wells MW-24 and MW-83 are shallow wells and well MW-23 is a deeper well paired with MW-24. With the exception of strontium and sulfate, concentrations of all reportable parameters have remained below the water quality guidelines in the upgradient wells during the period of record. Strontium concentrations have exceeded the water quality guideline of 0.05 mg/l, and sulfate concentrations have generally exceeded the water quality guideline of 250 mg/l at the upgradient wells. It will become apparent throughout this report that the strontium water quality guideline of 0.05 mg/l is probably below the background concentration of this parameter across the site. The strontium water quality guideline, as currently stated, is generally not achievable at this site due to natural background concentrations.

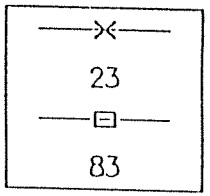
Downgradient Wells

Downgradient wells MW-17, MW-18, MW-22, and MW-87 (Figures 6 and 7), all of which are shallow, have exhibited variable responses over time, depending upon the specific parameter and well location being examined. For example, wells MW-17 and MW-18, which are at the downgradient (southern) edge of Pond #93, have exhibited similar responses for boron, chloride, strontium, and sulfate. In each case, these constituents were at consistently low concentrations until at least 1983, after which time steady increases in concentration were observed for varying lengths of time. Arsenic and selenium concentrations have not shown similar increases over time at any of the downgradient wells.

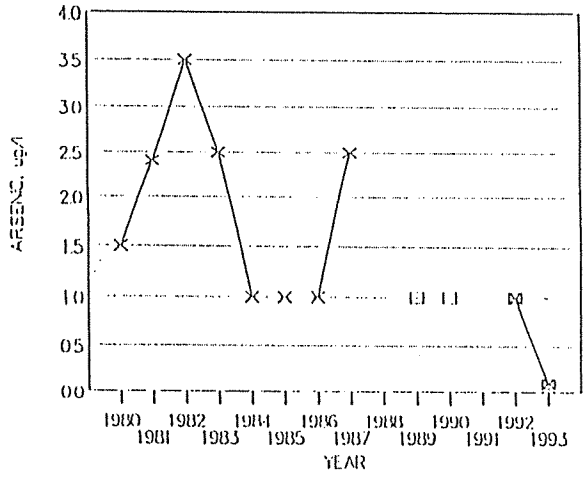
At well MW-17, concentrations of boron, chloride and sulfate appeared to peak in approximately 1991, with fairly constant or slowly declining concentrations since that time. The concentrations of strontium at well MW-17 appear to have peaked in approximately 1989, with a steady decline since then. These same parameters have exhibited similar responses at well MW-18, with the exception that recent declines in boron, chloride and sulfate are not as apparent as at well MW-17. Concentrations of chloride have generally exceeded the water quality guideline of 250 mg/l at wells MW-17 and MW-18 since approximately 1990. Concentrations of sulfate have generally exceeded the water quality guideline of 250 mg/l at these wells since approximately 1986. Boron exceeded the water quality guideline of 0.75 mg/l at wells MW-17 and MW-18 in 1993.

Well MW-87, situated downgradient to sidegradient (southeast corner) of Pond #93, has a short period of record (1989 to the present). Sulfate has typically exceeded the water quality guideline during the period of record. However, the concentrations of sulfate have been below the guideline since 1992.

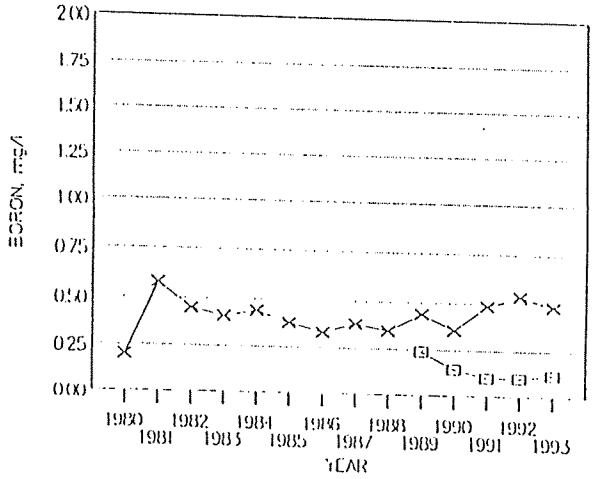
Well MW-22, situated downgradient to sidegradient (west edge) of Pond #93, has only been sampled twice in recent years (1987 and 1993). Sulfate has exceeded the water quality guideline of 250 mg/l in both years (398 and 302 mg/l in 1987 and 1993, respectively).



Strontium has been consistently detected above the water quality guideline at all downgradient wells in this subdivision.



Additional Wells



Additional wells MW-16, MW-20, MW-21, MW-90, and MW-91 (Figures 8 and 9) in this subdivision are all downgradient or sidegradient to the evaporation ponds. As with the downgradient wells discussed above, these wells have exhibited variable responses, depending upon the specific parameter and well locations. Wells MW-16, MW-20 and MW-21, which have the longest periods of record (1980 to the present), have consistently exhibited non-detectable or low concentrations for all reportable parameters except sulfate. Sulfate has consistently been detected at concentrations above the water quality guideline of 250 mg/l at wells

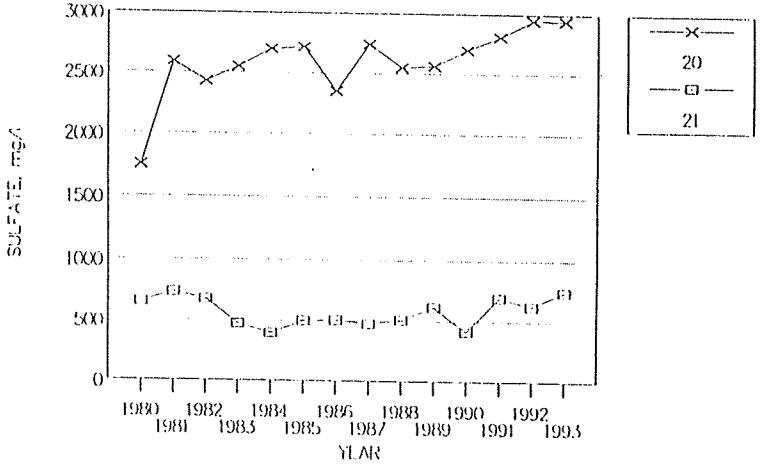

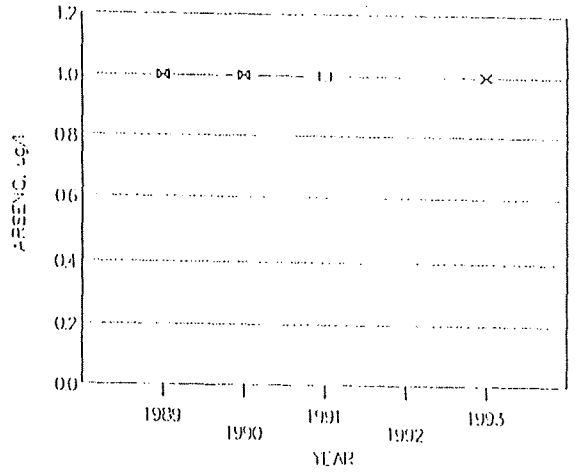

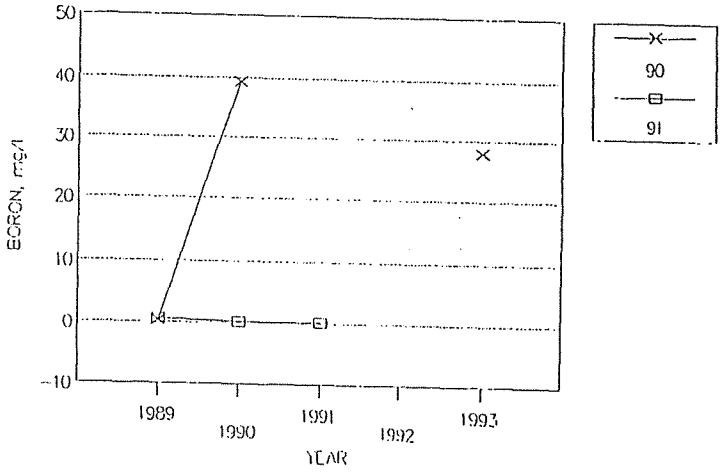

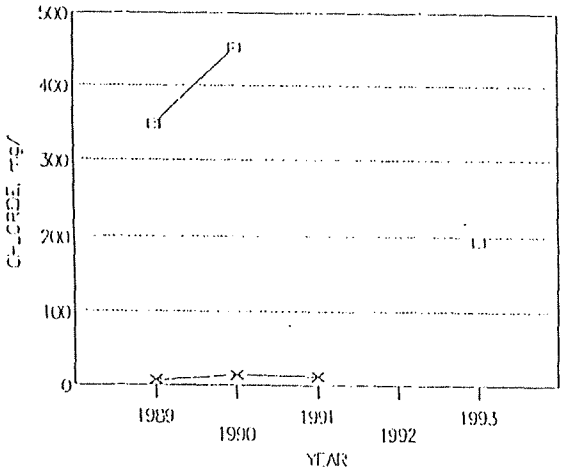

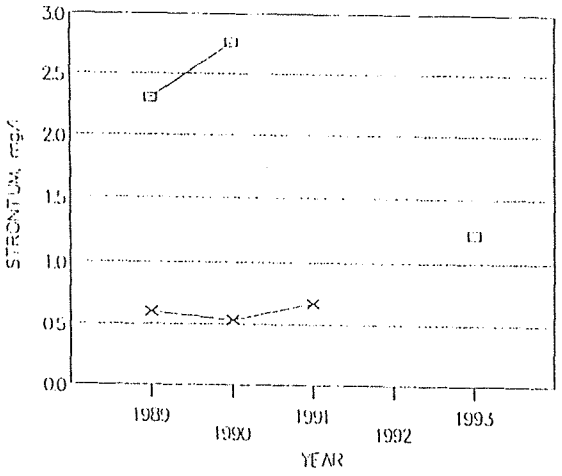

FIGURE 9. WATER QUALITY TREND CHARTS

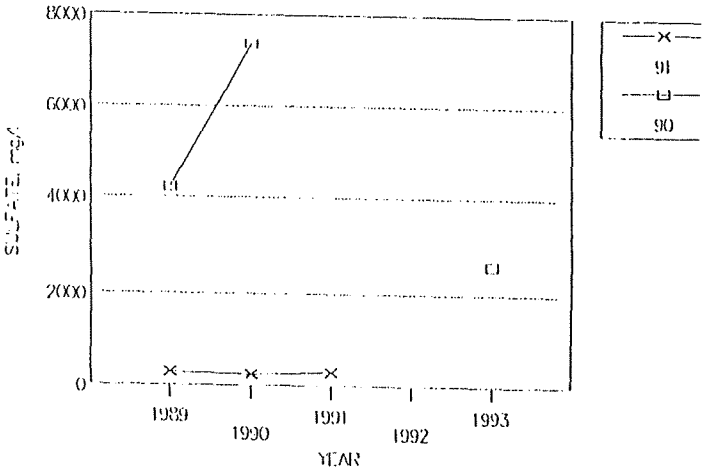


SUBDIVISION A ADDITIONAL WELLS

MW-20 and MW-21 throughout the period of record. These two wells, along with downgradient well MW-22, form a nest of three wells completed at different depths, near the western edge of Pond #93. The sulfate concentration has typically been highest in the deepest well (MW-20) of this nest, with the concentrations exhibiting a very slow increase over time.

Additional downgradient wells MW-90 and MW-91 have shorter periods of record, starting in 1989. Well MW-90 is a shallow well near the southwest corner of Pond #94 and well MW-91 is a deeper well at the downgradient edge of Pond #94. At well MW-91, sulfate has only marginally exceeded the water quality guideline of 250 mg/l during the short period of record. Well MW-91 has not been sampled since 1991. At well MW-90, both chloride and sulfate concentrations have exceeded the respective water quality guidelines; however, the 1993 sample results exhibit significantly reduced concentrations of both parameters (with chloride falling below the water quality guideline) compared to earlier in the period of record.

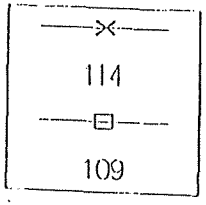
Surface Water

Water samples have been collected from the evaporation ponds to document operational conditions and to evaluate potential impacts to ground water near the ponds (Figure 10). Data from surface water location SW-109 are limited because Evaporation Pond #94 was not used until 1992. Data from SW-114 (from Evaporation Pond #93) are more extensive since the pond has been used since 1983. Pond water quality data, compared to ground water quality criteria, indicate elevated concentrations of boron, chloride and sulfate. Concentrations of these parameters showed a steady increase until the early 1990s, when both ponds were taken out of service and repaired.

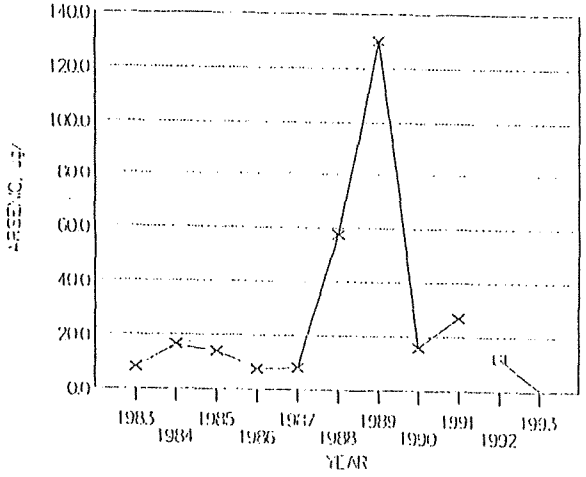
Influence of Pond Repairs

While it is apparent that there have been ground water impacts at several of the downgradient wells in Subdivision A, it appears that the repairs at Ponds #93 and #94 have started to influence the concentrations of several of the parameters. In particular, this is evidenced by the response at well MW-17 at the downgradient edge of Pond #93, which has shown a steady decline in boron, chloride and sulfate concentrations since 1991. Additional downgradient well MW-90 also showed a reduction in chloride and sulfate concentrations in the 1993 sample.

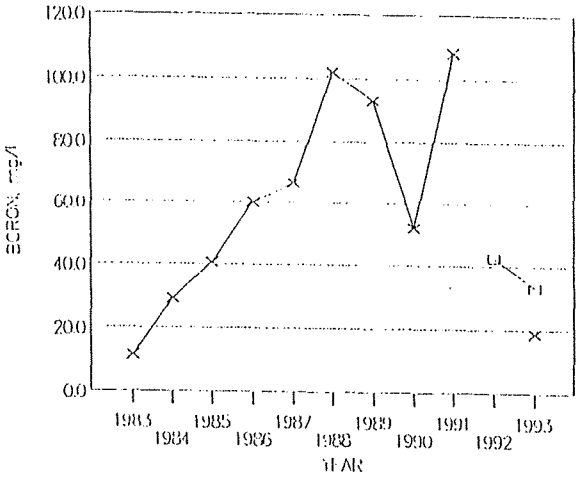
Statistical Analysis



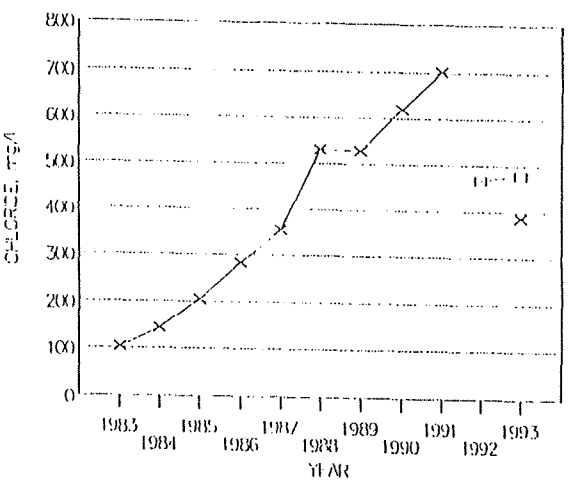
Use of Historical Monitoring Data



The discussion above, along with examination of the water quality data plots for this subdivision, provide a basis for evaluating water quality conditions at the monitoring locations. Additional data plots in Appendix E include various exploratory statistical methods to assist in determining the applicability of statistical analyses to the data.



It is apparent from the water quality data plots that several of the downgradient wells have exhibited water quality impacts during the period of record. Although such impacts are apparent for several of the reportable parameters (boron, chloride, strontium, and sulfate), the concentrations are not necessarily above water quality guidelines (e.g. increased concentrations of boron and strontium at wells MW-17 and MW-18 are still below the guidelines).



Because there have been obvious impacts to ground water, there is no use in conducting an ongoing comparison between downgradient and upgradient wells. Rather, current conditions at various locations will be examined and methods employed to detect changes in the future. Water quality data from the early period of record prior to the appearance of ground water impacts will be used to represent the non-impacted conditions at each location.

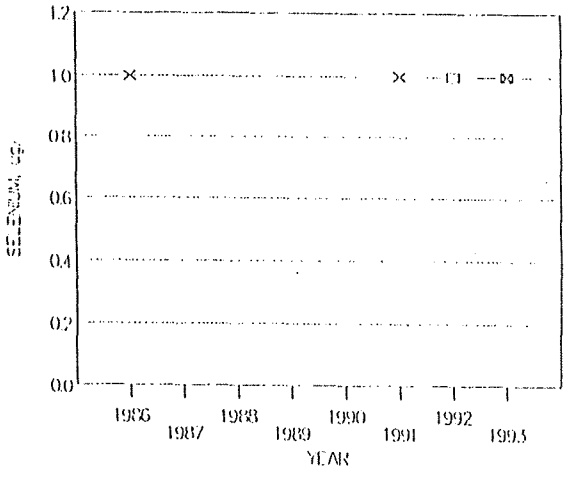


FIGURE 10. WATER QUALITY TREND CHARTS
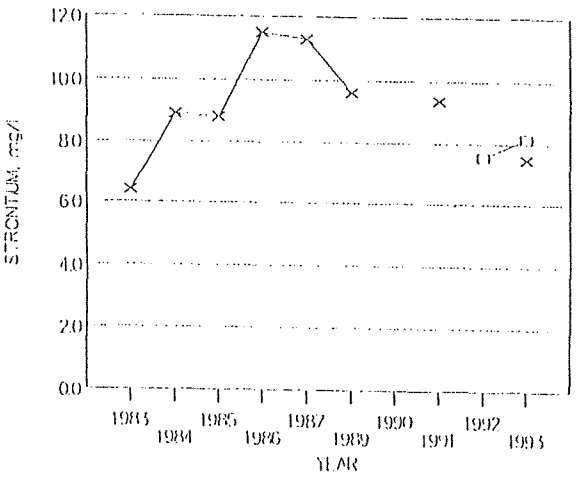
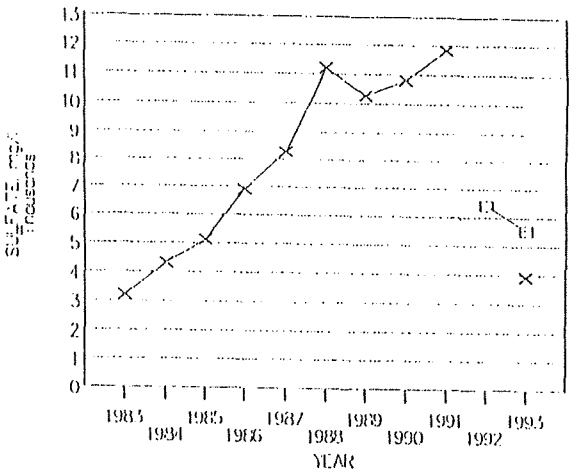
SUBDIVISION A SURFACE WATERS





Selection of a Statistical Test

Two approaches are potentially useful to CP in continuing to assess ground water quality conditions in Subdivision A. One approach is to continue monitoring changes in downgradient levels of the reportable parameters. This is best performed with time series graphics, which CP already produces and submits to NDSDH each year, in accordance with permit requirements. The other approach is to compare values in every well with values during the early portion of the period of record, before effects in ground water were observed at several of the downgradient wells.

One appropriate method to compare ongoing monitoring values with historical values is to develop a *one-sided upper tolerance limit* from the historical data. Specific details regarding implementation of the tolerance limit method are provided in Section 3 of Appendix D. A summary of the method, including application of the method to the data in this subdivision, is provided below.

A tolerance limit uses sample data to place an outer limit (an upper limit in the case of a one-sided test) on the concentrations that can be expected to represent non-impacted conditions. This implies that there is a threshold concentration outside of which a measured value is assumed to no longer be within the typical range of historical (in this case, assumed to be non-impacted) data concentrations. In a ground water monitoring situation, a one-sided upper tolerance limit places an upper bound on a high percentile of the data. This means that, if this upper bound is exceeded, the measured value is tentatively assumed to represent a ground water impact. The upper bound is generally selected such that between 90% and 99% of the data record representing non-impacted conditions should continue to fall below the threshold value over time. This percentile is often referred to as the *coverage*. USEPA regulations and guidance documents for RCRA ground water monitoring recommend (but do not require) coverage of 95%. Therefore, a 95% coverage value is utilized herein.

In addition to the coverage, as defined above, the tolerance limit requires that a certain *confidence level* be specified. The confidence level defines the certainty with which the statistical method is likely to properly identify an exceedance of a threshold value. In the tolerance limit example, if a confidence level of 90% is utilized with 95% coverage, the implication is that there is 90% certainty that a maximum of 5% of future measured concentrations will exceed the calculated tolerance limit, even if there are no ground water impacts.

In application of the tolerance limit method herein, a 95% confidence level will be utilized, along with the 95% coverage value. As with the coverage value, USEPA regulations and guidance documents for RCRA ground water monitoring recommend (but do not require) a confidence level of 95%. For RCRA monitoring applications, the confidence is not allowed to exceed 95%.

A tolerance limit is a useful screening method that may be used for examining future measured concentrations in ground water samples. Concentrations of a parameter that exceed the tolerance limit developed from historical data in one well should be considered significantly high values. The calculated tolerance limit will not change in time, because it is developed from historical data and is not normally updated using new data.

Methods and Calculations

The tolerance limits utilized in this analysis are computed with upper one-sided 95% coverage and 95% confidence levels. The tolerance limits are computed by adding a multiple, K, of the historical standard deviation to the historical mean. The value of K depends on the coverage, the confidence, and the number of historical values used. Section 3 of Appendix D develops the theory and provides typical values of K. The period used to develop the historical mean and standard deviation for each monitoring well extends from 1979 through 1983, the approximate period prior to when ground water impacts appeared to be evident.

For Subdivision A, all four parameters -- boron, chloride, strontium, and sulfate -- were measured 11 times in each well during 1979 through 1983, with the following exceptions. Wells MW-83 (upgradient), MW-87 (downgradient), MW-90 (downgradient), and MW-91 (downgradient) were not installed during the period from 1979 through 1983. For these four wells, only four to six measurements of each reportable parameter are available, with all measurements obtained after 1983, during a period when water quality changes were occurring at the downgradient wells. Therefore, until more data are obtained (to evaluate recent trends), it would not be appropriate to develop tolerance limits for these four wells. Tolerance limits were not developed for well MW-24 (upgradient), which has a limited number of measurements, ending in 1980.

Table 3 summarizes the resulting tolerance limits calculated for the monitoring wells with sufficiently long historical periods of record. Tolerance limits were not calculated for arsenic or selenium due to the large number of non-detects during the period of record. The value of the statistical parameter, K, for 11 historical values is 2.815 (see Section 3 in Appendix D). All values are in units of mg/l.

Error Rates

An upper bound, such as a one-sided upper tolerance limit, can be arbitrarily high. To limit it, one should elect to accept some risk that the upper bound be too low. This risk implies that there is a chance that a measured concentration appears to indicate an impact to ground water, when in fact, the concentration is within a statistically acceptable range. The risk acceptable to most regulatory authorities, including the USEPA (as required in 40 CFR 264.97 *et seq.*, for example) is 5%. This is the value we have used to compute upper tolerance limits. Because 24 tolerance limits have been independently computed, the expected number of limits that underestimate the true 95th percentile is 5% of 24, or 1.2. Most of these tolerance limits therefore overestimate the 95th percentiles.

Only 5% of subsequent data would be expected to exceed the 95th percentile of a distribution, provided that conditions did not change. Therefore, one future value exceeding a tolerance limit could be the result of that 5% chance. However, when several results in succession exceed a tolerance limit, or more than 5% in the subsequent monitoring history exceed the historical tolerance limit, a statistically significant change in conditions has likely occurred.

Discussion

The upgradient well, MW-23, has some of the highest tolerance limits. This is not unusual, because ground water conditions vary by location. Historically, in this 1979 to 1983 period, well MW-23 tended to exhibit slightly higher boron and chloride concentrations than the other wells in this subdivision. Likewise, additional downgradient wells MW-20 and MW-21 exhibited higher sulfate concentrations during that period of time, compared to other wells in the subdivision.

Recent concentrations at the upgradient well (MW-23) tend to fall beneath their tolerance limits. Results for all four parameters are consistently above the tolerance limits in the downgradient wells (MW-17, MW-18, and MW-22).

SUBDIVISION B

This subdivision, located in the northwest section of the plant site (Figure 11), encompasses a portion of the fly ash runoff basin and Evaporation Ponds #91 and #92. The fly ash runoff basin was constructed to collect runoff from a temporary fly ash disposal site that was never completed, hence the pond serves no purpose. Water quality sampling locations (with completion depths below ground surface for monitoring wells) monitoring this subdivision and reported herein are as follows:

Ground Water

Upgradient	Downgradient	Additional
MW-38 (25 ft)	MW-29 (28 ft)	MW-30(42.5 ft) [Downgradient]
	MW-32 (13 ft)	MW-31 (25 ft) [Downgradient]
	MW-80 (18 ft)	MW-79 (21 ft) [Downgradient]
		MW-81 (30 ft) [Downgradient]
		MW-82 (27 ft) [Downgradient]

Surface Water

SW-110
SW-113
SW-118

A summary of the historical usage of Ponds #91 and #92 in this subdivision is provided in Table 1. Pond #91 was out of service from 1984 through 1989, relined during the summer of 1990, and placed back in service in November 1990. Pond #92 was out of service in 1990, repaired in 1991, and has been in service since 1992.

Qualitative Discussion of Historical Water Quality Data

Time series data plots of the reportable parameter concentrations for the planned water quality monitoring locations in Subdivision B are provided in this section. Table 4 provides a summary of the most recent measured concentrations for Subdivision B in comparison to the water quality guidelines.

Wells MW-29 through MW-32 and MW-38 have a period of record extending from 1980 to the present, whereas wells MW-79 through MW-82 have only been sampled since 1989. The following sections provide qualitative descriptions of water quality in the subdivision, based on an examination of water quality trends for the various monitoring wells and knowledge of the historical usage of the evaporation ponds within this subdivision.

Upgradient Wells

Upgradient well MW-38 (Figure 12) documents ambient conditions and shows no obvious trends during the period of record, with the exception of a temporary increase in chloride concentrations between 1988 and 1992. During the period of increasing chloride concentrations the water quality guideline of 250 mg/l was never exceeded (maximum chloride concentration was 12 mg/l in 1992). Although no trends in strontium or sulfate concentrations are evident at well MW-38, these two parameters have generally exceeded the respective water quality guidelines of 0.05 mg/l and 250 mg/l throughout most of the period of record at this well.

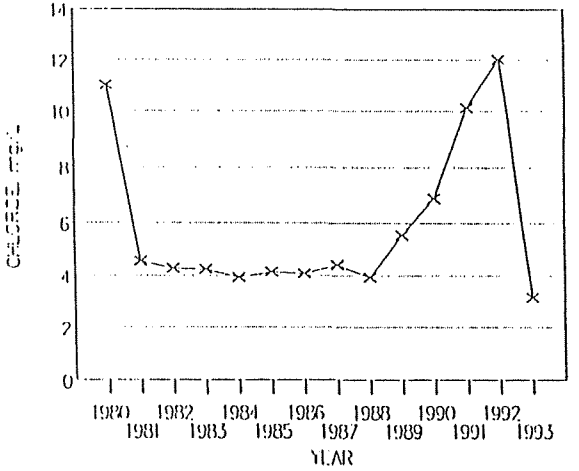

FIGURE 12. WATER QUALITY TREND CHARTS

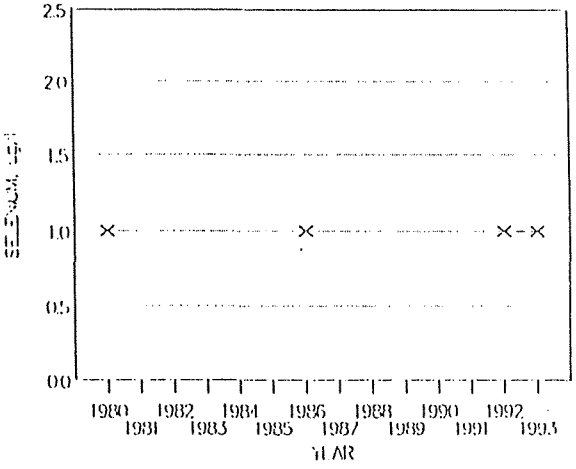
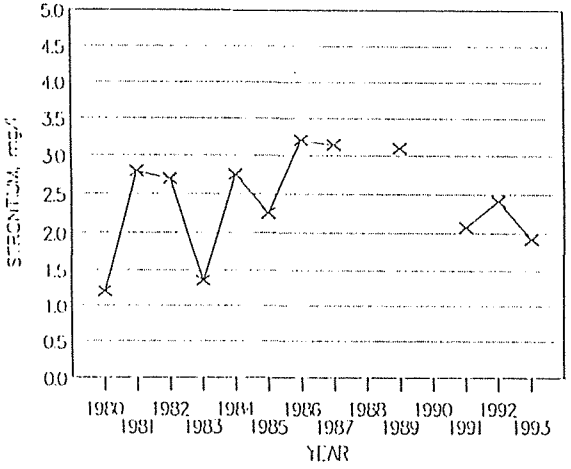
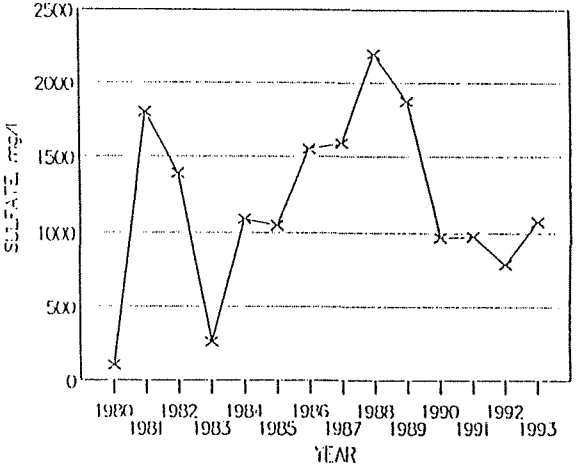


SUBDIVISION B UPGRADIENT WELLS



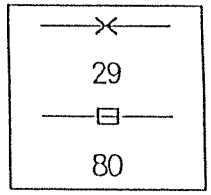


Downgradient Wells

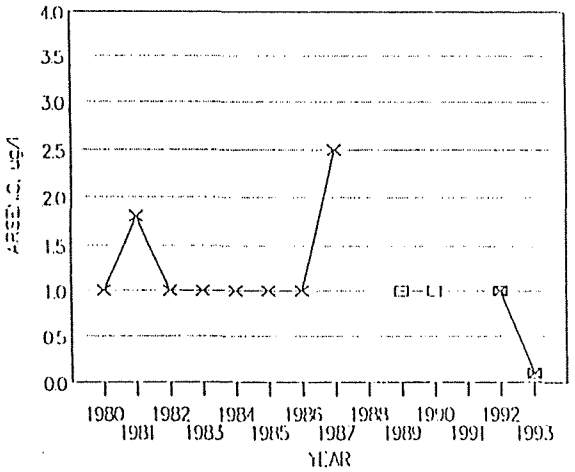
Downgradient wells MW-29 (Figure 13) and MW-32, which have the longest periods of record and are situated along the southeastern edge of Pond #91, have exhibited similar water quality responses over time. For example, several of the reportable parameters (including chloride, strontium and sulfate) exhibited a rapid upward spike in concentration in 1981, followed by a rapid (1- to 2-year) decline to levels that have been consistently observed since then. The boron concentration at well MW-32 has exhibited a similar trend, with the exception that the peak concentration occurred approximately one year later than for the other parameters. The boron concentration at well MW-29 also exhibited a similar trend, but the increasing concentrations occurred over a 2- to 3-year period through 1984, and have declined slowly since then. Downgradient well MW-80 (Figure 13), which has only been sampled since 1989 and is situated at the southwestern corner of Pond #91, exhibited a decrease in concentrations of chloride, strontium and sulfate in 1993, following approximately 3 years of increasing concentrations.

Boron has exceeded the water quality guideline of 0.75 mg/l at downgradient wells MW-29 and MW-80 for the past several years. Strontium and sulfate concentrations have generally exceeded their respective water quality guidelines of 0.05 mg/l and 250 mg/l throughout most of the period of record at all three downgradient wells (MW-29, MW-32 and MW-80). Selenium exceeded the water quality guideline of 0.01 mg/l at wells MW-29 and MW-32 in 1993.

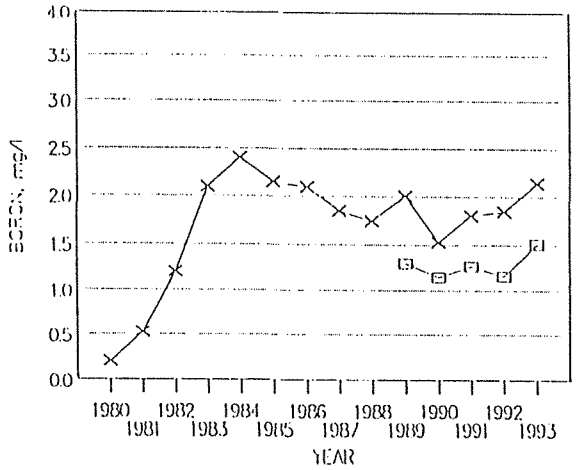
Additional Wells



Additional wells MW-30, MW-31, MW-79, MW-81, and MW-82 (Figures 14, 15 and 16) in this subdivision are all downgradient or sidegradient to the evaporation ponds. As with the downgradient wells discussed above, the additional wells have exhibited variable responses, depending upon the specific parameter and well locations. Additional wells MW-30 (deep) and MW-31 (mid-depth) are nested with downgradient well MW-32 (shallow), discussed above. Wells MW-30 and MW-31 exhibited a response similar to MW-32, including a rapid spike in boron, chloride, strontium, and sulfate during 1980 and 1981. A rapid decline in boron and sulfate concentrations over time is evident at well MW-30, with a more slow decline in boron, chloride and sulfate at well MW-31. Selenium has not been detected at additional downgradient well MW-30 during intermittent sampling since 1980, but has been detected consistently at MW-31. Strontium concentrations have remained at a fairly consistent level at both wells since the initial increase in the early 1980s. The overall water quality response at the nest of wells (MW-30, MW-31 and MW-32) can be summarized as follows: (1) the most obvious impact (highest concentrations) occurred at the shallowest well (MW-32), with steadily decreasing concentrations with depth (MW-31 and MW-30); (2) followed by decreases in concentrations that occurred most rapidly in the shallowest well.



Additional downgradient wells MW-79, MW-81 and MW-82 have shorter periods of record, starting in 1989. All three wells are completed at approximately the same depth (21 to 30 feet below grade) and are situated along the downgradient edge of Pond #92. Only well MW-79 was sampled in 1993. Boron, selenium, strontium and sulfate all exceeded their respective water quality guidelines at well MW-79.



Selenium concentrations have consistently been above the water quality guideline of 0.010 mg/l for the past several years at well MW-31 (mid-depth), but have not been detected at the deeper well (MW-30) of the nest. Concentrations of strontium and sulfate have consistently exceeded their respective water quality guidelines of 0.05 mg/l and 250 mg/l at both the mid-depth (MW-31) and deep (MW-30) wells of the nest.

Surface Water

Water quality trend charts for surface waters in Subdivision B are shown in Figures 17 and 18. Evaporation Pond #92 has been in service from 1980 to the present, except for repair activities in 1990 and 1991. Water quality data from surface water sampling location SW-105 has shown elevated concentrations of boron, chloride, strontium, and sulfate. Concentrations are dependent upon operational activities.

Evaporation Pond #91 was used from 1980 to 1983, repaired in 1990, and has been in use from 1990 to the present. During 1984 to 1989, a small area (a few acres) of water was present on the south end of the pond, from which samples were collected. The water was primarily ground water leakage from Evaporation Pond #92, and an occasional limited discharge of process water. Elevated concentrations of boron, chloride, strontium, and sulfate have been detected at this location. The concentrations reflect a moderate level of concentrations during initial pond usage in the early 1980s. Concentrations decreased in the mid- to late-1980s due to a mixture of ambient ground water and leakage from Evaporation Pond #92. Increased concentrations in the early 1990s resulted from renewed use of the pond for handling process water.

The mine surge pond (surface water sampling location SW-118) is used by Falkirk Mining Company. Concentrations are near or below ground water quality criteria.

Location SW-110 was intended to monitor conditions at the Fly Ash Runoff Basin. This area was never developed for this purpose. The concentrations are near or below ground water quality criteria and reflect ambient conditions.

Influence of Pond Repairs

Increased concentrations of several of the parameters (as discussed above) occurred soon after Ponds #91 and #92 were placed into service in 1980. In general, the parameter concentrations have been declining or remaining steady since the early- to mid-1980s. The declining concentrations do not appear to correspond to repair of the evaporation ponds. However, the trends may be masked by a lag time for the constituents to dissipate from beneath the large pond (Pond #91), which was out of service from 1984 to 1989, as well as continued use of the smaller pond (Pond #92) until 1990.

Statistical Analysis

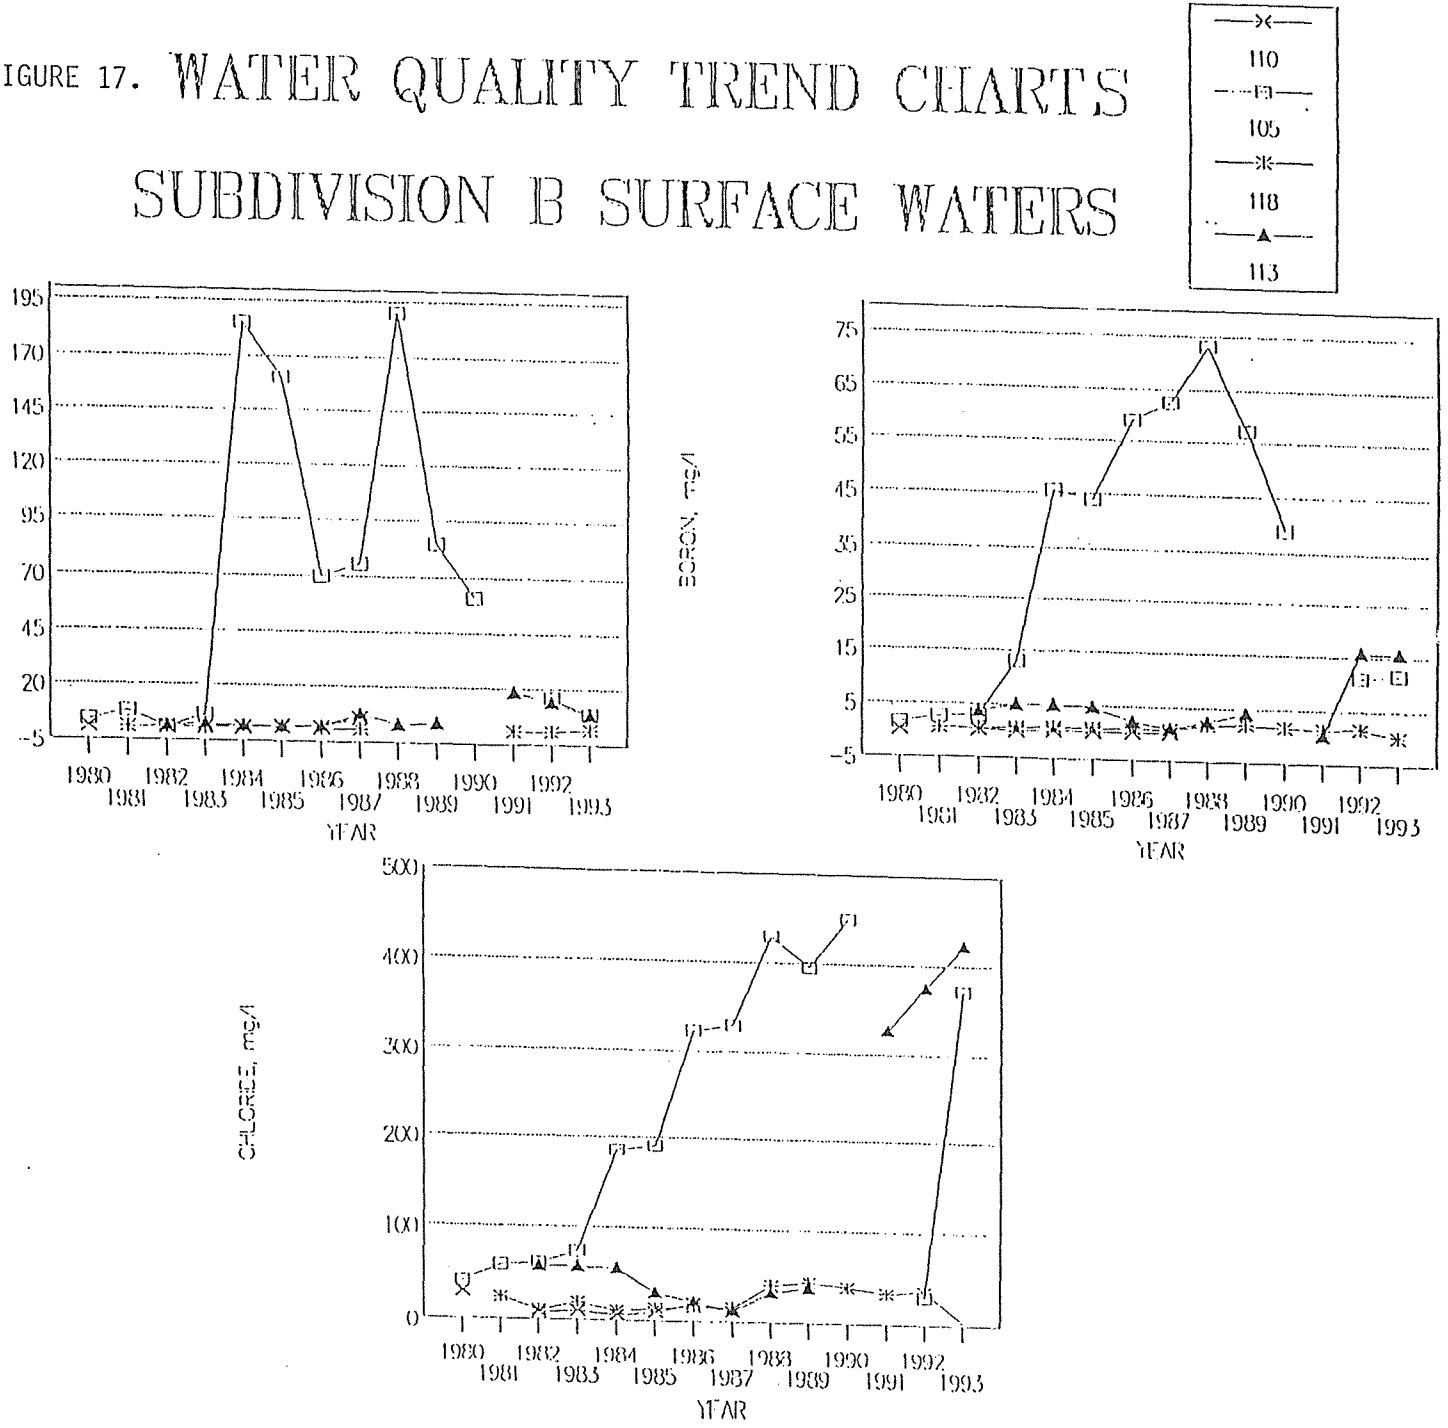
Use of Historical Monitoring Data

The discussion above, along with examination of the water quality data plots for this subdivision, provide a basis for evaluating the water quality conditions at the monitoring locations. Additional data plots in Appendix E include various exploratory statistical methods to assist in determining the applicability of statistical analyses to the data.

In the downgradient and additional wells, many parameters exhibited a rapid upward spike in concentration in 1981, followed by a quick (two-year) decay to levels consistently observed since then. For some parameters (e.g. chloride in downgradient well MW-29 and additional downgradient well MW-31, and sulfate in downgradient well MW-32), this decay has continued. In either circumstance, more power to characterize recent data will be achieved by removing the pre-1983 data from the data set.

FIGURE 17. WATER QUALITY TREND CHARTS

SUBDIVISION B SURFACE WATERS



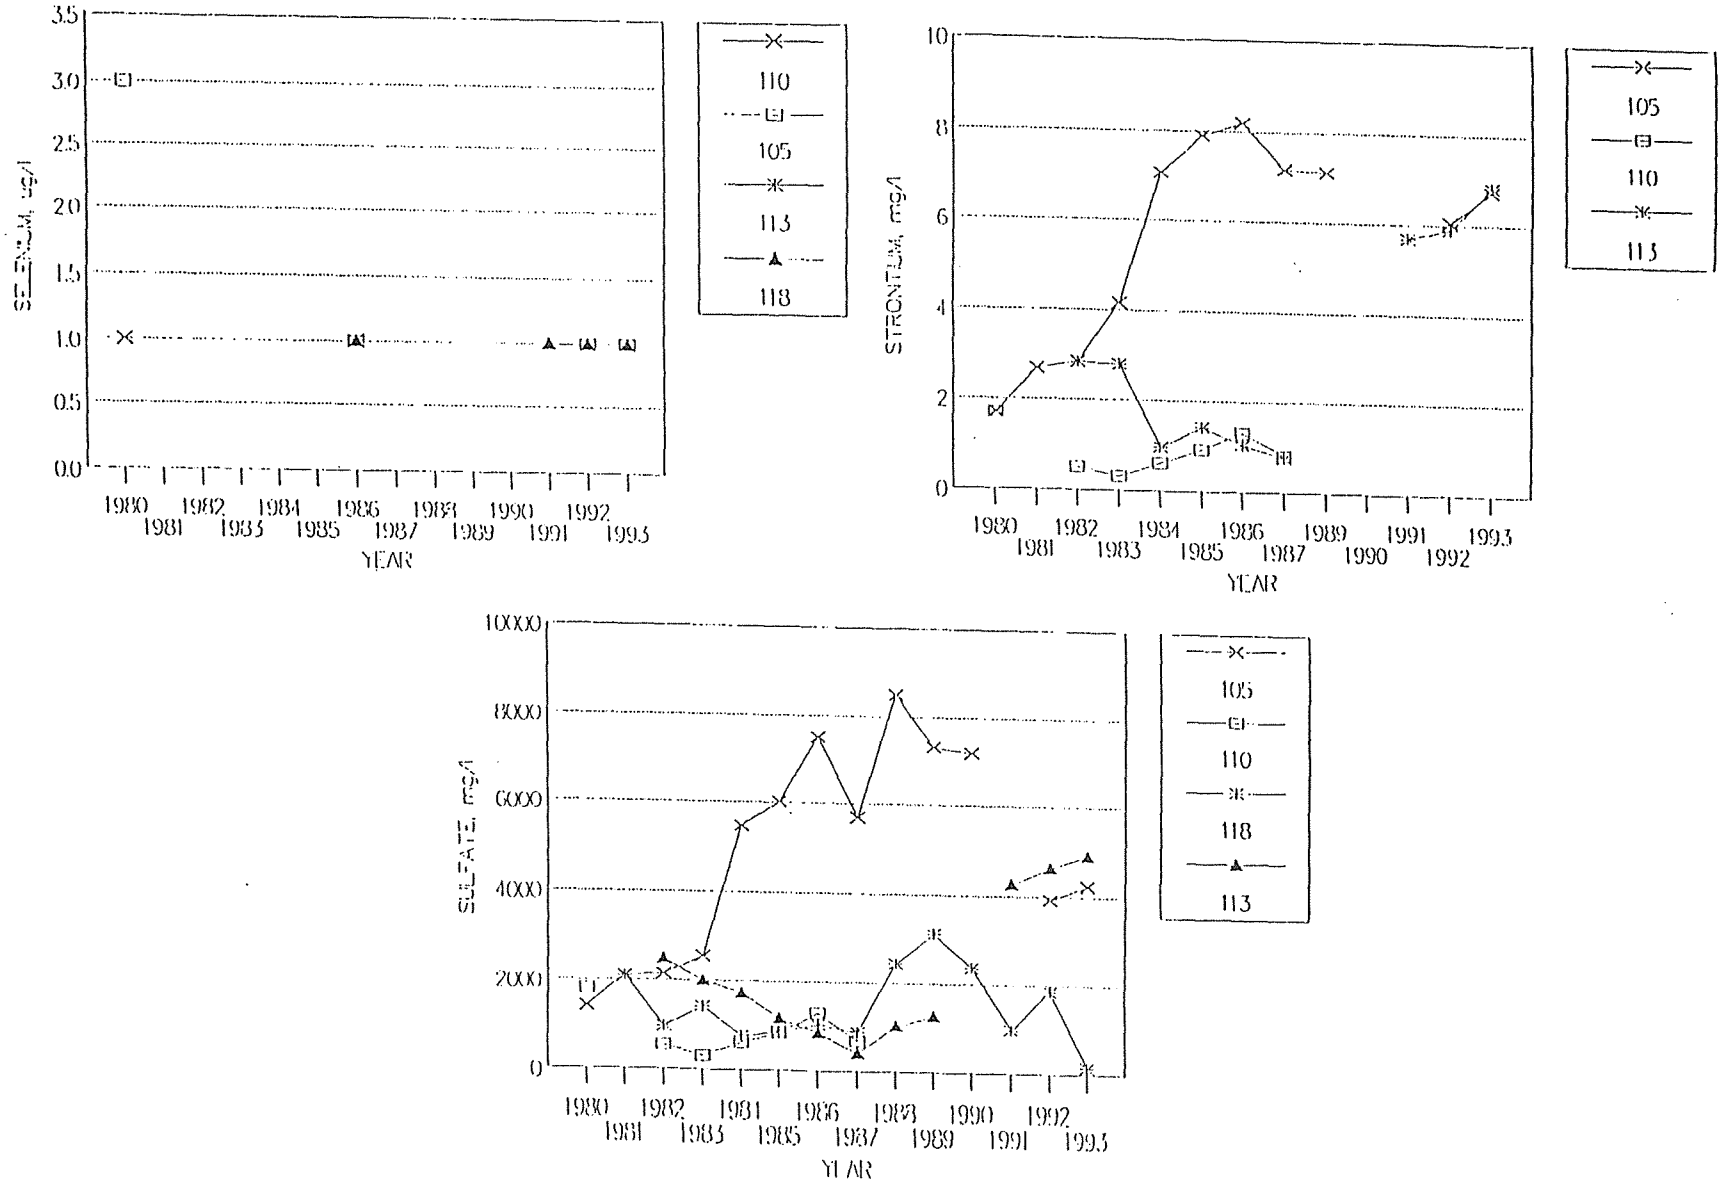


FIGURE 18. WATER QUALITY TREND CHARTS

SUBDIVISION B SURFACE WATERS

Selection of a Statistical Test

With one exception, monitoring histories (unique combinations of well and parameter) are either stable or changing at a regular rate from 1983 through 1993. The exception is boron in downgradient well MW-29, which increased sharply (about an order of magnitude) from a near-background baseline between 1982 and 1984, and has slowly oscillated since then. The statistical graphics plots provided in Appendix E, consisting of control charts (for the stable histories) and regression lines (for the trending histories) incorporate appropriate statistical tests. Specific details regarding implementation of the regression line and control chart methods are provided in Sections 1 and 2 of Appendix D, respectively.

The control charts monitor histories for sudden sharp deviations or low-level long term deviations from historical conditions specific to each well and parameter. The charts provide a visual means of detecting deviations from a "state of control", implying changes from the long-term stable condition. The regression lines quantify the trend rates and implicitly project future values. Deviations can be identified visually from the time series plus trend line plots.

Methods and Calculations

Section 1 of Appendix D describes the calculations for determining regression lines. The method developed by the EPA for RCRA ground water monitoring is recommended for control charts. Section 2 of Appendix D describes the calculations for this method.

Error Rates

A history with no real trend can sometimes appear to trend because of coincidentally trending random variations in the observations. The recommended regression method will falsely identify such a trend less than 1% of the time.

Error rates for control charts are measured by expected lengths of runs of in-control points. For a truly stable history, this run length should be long. For a trending history, this run length should be as short as possible. The EPA fine-tuned the recommended method to achieve expected in-control run lengths of several hundred (monitoring periods) for stable histories and expected in-control run lengths between 4 and 8 periods for trending histories.

Discussion

Although it is meaningful to compare parameter concentrations between upgradient and downgradient wells, such a comparison could be deceptive. For the stable histories--and this is most of them in this subdivision--the long term averages and standard deviations adequately characterize ground water quality. After a long period of monitoring, so much data will be available that almost infinitesimal differences in long term average will be statistically significant--but unimportant, from a hydrogeological perspective. Moreover, the qualitative comparison of data across upgradient wells reveals considerable spatial variation in natural ground water quality. Therefore, even in pristine conditions, comparisons of any two wells will usually yield significant differences.

The changes in boron in downgradient well MW-29 follow a pattern not revealed by any other monitoring history in this subdivision. Although regression indicates a long term trend, this is not to be trusted because the shape of the trend does not approximate a straight line--most of it occurred during the first three years of a fourteen year monitoring history.

Selenium is consistently detected in downgradient well MW-32 and additional downgradient well MW-31. Its statistical distribution is skewed. Examining the results after a cube-root or logarithmic transformation identifies three distinct time frames: before 1983, between 1983 and mid-1986 inclusive, and after mid-1986. During the earliest period, results in both wells were similar, ranging from non-detect (<1 mg/l) to 520 mg/l. Suddenly, concentrations in both wells fell consistently into the range from 3 to 63 mg/l during the middle period. In the latest period, concentrations appear lower in well MW-32 while they have been highly variable in well MW-31, reaching 775 mg/l.

There is no clear relationship between the time periods exhibited by the data and the operating history of this subdivision. As with boron in downgradient well MW-29, these changes have been so complex and pronounced that perhaps the best way to test the results is again by plotting the time series graphics to observe each new result in its historical context.

SUBDIVISION C

This subdivision, located in the southwest section of the plant site (Figure 19) includes the Coal Pile Runoff Basin, River Water Holding Basin, Extended Basin, Generation Buildings, and borders the western edge of South Ash Pond Cell #91. The water quality sampling locations (with completion depths below ground surface for monitoring wells) monitoring this subdivision and reported herein are as follows:

Ground Water

Upgradient	Downgradient	Additional
~~MW-58 (22.5 ft)~~	MW-62 (43.3 ft)	MW-63(42.4 ft) [Downgradient]
MW-61 (44.1 ft)	MW-64 (24.6 ft)	MW-65 (24 ft) [Downgradient]
MW-76 (19.5 ft)		

The local ground water flow direction in this subdivision is toward the northeast. However, due to expected radial ground water flow conditions away from the Extended Basin, additional wells MW-63 and MW-65 are also considered to be hydraulically downgradient.

Surface Water

SW-104
SW-107

A summary of the historical usage of the River Water Holding Basin and the Extended Basin in this subdivision is provided in Table 1. The River Water Basin and the Extended Basin have both been in service since 1979. Repairs were made to the River Water Basin in 1984.

Qualitative Discussion of Historical Water Quality Data

Time series data plots of the reportable parameter concentrations for the planned water quality monitoring locations in Subdivision C are provided in this section. Table 5 provides a summary of the most recent measured concentrations for Subdivision C in comparison to the water quality guidelines.

Monitoring of all wells in this subdivision except upgradient well MW-76 began in late 1988. Well MW-76 has been monitored from 1989 to 1991. The following sections provide qualitative descriptions of water quality in the subdivision, based on an examination of water quality trends for the various monitoring wells and knowledge of the historical usage of the evaporation ponds within this subdivision.

[1] WQ Guide = Water Quality Guideline

Upgradient Wells

Upgradient wells MW-58, MW-61 and MW-76 (Figures 20 and 21) document ambient conditions and show no obvious trends in the reportable parameters during the period of record. Strontium and sulfate have been consistently above their respective water quality guidelines of 0.05 mg/l and 250 mg/l at the upgradient wells throughout the period of record. Well MW-58 was not sampled in 1993 (it will be out of service in 1994) and MW-76 was sampled only for field parameters, as noted in the 1993 monitoring plan.

Downgradient Wells

Downgradient wells MW-62 (deep) and MW-64 (shallow), shown in Figure 22, comprise a nest situated near the northeastern corner of the Extended Basin. The shallow well (MW-64) has typically exhibited higher concentrations of the reportable parameters than the deep well (MW-62). For most reportable parameters these two downgradient wells have exhibited significantly higher concentrations than the upgradient wells (MW-58, MW-61 and MW-76) in this subdivision.

Boron has typically exceeded the water quality guideline of 0.75 mg/l at the shallow downgradient well (MW-64), although decreasing concentrations have been noted in the last three years. Boron concentrations in the deeper downgradient well (MW-62) have exhibited an increasing trend, with the most recent measurement (0.77 mg/l in August 1993) slightly exceeding the water quality guideline. The most recent chloride measurements have been below the water quality guideline of 250 mg/l at both downgradient wells. The limited number of samples analyzed for strontium (three at both wells) do not exhibit a trend; however, all samples have exceeded the water quality guideline of 0.05 mg/l. Sulfate concentrations have typically exceeded the water quality guideline of 250 mg/l at the nested downgradient wells (MW-62 and MW-64), with somewhat higher concentrations in the shallower well (MW-64).

Additional Wells

Additional wells MW-63 and MW-65 (Figure 23) in this subdivision are considered hydraulically downgradient of the Extended Basin, since radial ground water flow is expected from the basin. Wells MW-63 (deep) and MW-65 (shallow) form a well nest at this location. These additional wells exhibit similar responses to nested downgradient wells MW-62 and MW-64 discussed above, except that the concentrations of most reportable parameters are lower at wells MW-63 and MW-65. In recent years, the only reportable parameters which have been higher at these latter wells are strontium (wells MW-63 and MW-65) and selenium (well MW-65 only). The shallow well (MW-65) has typically exhibited higher concentrations of the reportable parameters than the deep well (MW-63).

Strontium and sulfate concentrations have exceeded the respective water quality guidelines of 0.05 mg/l and 250 mg/l at the additional downgradient wells (MW-63 and MW-65) throughout the short period of record. In addition, the selenium concentration of .125 mg/l measured in 1993 at shallow well MW-65 slightly exceeded the water quality guideline of 0.01 mg/l for that parameter.

Surface Water

Surface water location SW-104 (Figure 24) is collected from the River Water Holding Basin (RWHB). All parameters are below the ground water quality guidelines. The source of this water is the Missouri River, which is the initial water source for the generating plant.

The Extended Basin (SW-107 - Figure 24) exhibits elevated concentrations of the tested parameters, especially sulfate. The parameters in this process water become concentrated as the water passes through the evaporative cooling system.

SUBDIVISION C SURFACE WATERS

Influence of Pond Repairs

The period of record for the monitoring wells began in 1988 in the vicinity of the Extended Basin. The repair of the RWHB in 1984 had limited influence on the monitoring wells around the Extended Basin because the RWHB is downgradient of the Extended Basin.

Statistical Analysis

Use of Historical Monitoring Data

The discussion above, along with examination of the water quality data plots for this subdivision, provide a basis for evaluating the water quality conditions at the monitoring locations. Additional data plots in Appendix E include various exploratory statistical methods to assist in determining the applicability of statistical analyses to the data.

Up to eight observations are available in the monitoring histories for the wells in Subdivision C. For many of the downgradient wells, this is a sufficient number to identify statistically significant regular trends. It is not enough to begin control charts; as Section 2 of Appendix D states, the first eight monitoring periods are used as a "learning period" to establish historical means and standard deviations.

Selection of a Statistical Test

All downgradient and additional wells either have significantly higher concentrations of most reportable parameters (except strontium) than the upgradient wells, or they exhibit significant increases in concentration. A good method to establish this (in the absence of significant trends) would be Analysis of Variance (ANOVA), assuming that the data were normally distributed. However, there is evidence of significant trends in the deeper downgradient wells (MW-62 and MW-63), and concentrations of sulfate and chloride in the shallow downgradient wells (MW-64 and MW-65) are so much higher than in upgradient wells MW-58, MW-61 and MW-76, that it is pointless to conduct this formal test. The strontium concentrations are not significantly different among wells because only three measurements are available at each well. Finally, although boron concentrations in well MW-64 are significantly higher than upgradient concentrations, in well MW-65 they appear to be significantly lower than upgradient concentrations.

For these reasons, together with the reasons provided in the discussion of Subdivision B, ground water monitoring data in this subdivision should be analyzed on an intra-well basis using control charts and linear regression.

Methods and Calculations

See the previous discussion for Subdivision B and Sections 1 and 2 of Appendix D.

Error Rates

See the previous discussion for Subdivision B.

Discussion

Concentrations tend to be slightly, but significantly, different between the two upgradient wells. The appropriate test to establish this would be a paired t-test. However, the results are evident in the statistical graphics plots provided in Appendix E, because the distributions of the data often do not overlap between the

two wells at all. Thus, chloride and sulfate have significantly higher concentrations in well MW-58; boron has significantly higher concentrations in well MW-61; strontium has not been observed enough times in either well to discriminate average concentrations; and arsenic and selenium have not been measured in well MW-58 at all. This information, nevertheless, is quantitative evidence of the natural variability of ground water quality conditions in upgradient wells at this facility.

Arsenic and selenium have rarely been measured, but are essentially undetected. Additional sampling during fall of 1994 will help evaluate the validity of the 1993 selenium detection of approximately .013 mg/l in additional downgradient well MW-65.

SUBDIVISION DI

This subdivision, located in the south central portion of the plant site (Figure 25), encompasses South Ash Pond Cells #91 and #92, and wells south and west of the ash pond. All other wells in this subdivision are located on the dike. Water quality sampling locations (with completion depths below ground surface for monitoring wells) in this subdivision and reported herein are as follows:

Ground Water

Upgradient	Downgradient	Additional
MW-57 (32.7 ft)	MW-10 (25 ft)	MW-9 (53 ft) [Downgradient]
MW-71 (45.5 ft)	MW-49 (19.9 ft)	MW-55 (18.5 ft) [Upgradient]
MW-74 (41 ft)	MW-50 (22.9 ft)	
	MW-54 (37.4 ft)	

Local ground water flow direction in this subdivision is toward the northeast; however, radial flow conditions may be occurring in the immediate vicinity of the ash pond cells.

Surface Water

SW-108
SW-126
SW-127

A summary of the historical usage of Ash Pond #91 and Ash Pond #92 is provided in Table 1. The former South Ash Pond (which included the entire area of Ash Pond #91, Ash Pond #92 and Plant Drain Pond #91) was placed into service in 1979 when the plant began operation. Visual evidence of leakage was observed on the north side of the South Ash Pond within a short time. The pond was taken out of service in 1980 and initially repaired in 1981. The East Ash Pond (current Section 16 Disposal Area) was put into service to replace the South Ash Pond during repairs. Ash Pond #91 was in service in 1989 and 1990, was dewatered during 1991, repaired during 1992, and placed back in service in 1993. Ash Pond #92 was repaired in 1989 and placed back in service in 1990.

In the mid-1980s it was determined that subsurface leakage was occurring from both the South Ash Pond and the East Ash Pond. The East Ash Pond was used while Ash Pond #92 (east half of the former South Ash Pond) was being constructed. The East Ash Pond (now the Section 16 Disposal Area, east of Ash Pond #92) is only used for dry ash storage, because of excessive leakage during use as a wet impoundment (the ash storage area is in the southwestern portion of the Section 16 Disposal Area, where lower permeability soils are present and where there is a greater separation between the ash and the ground water).

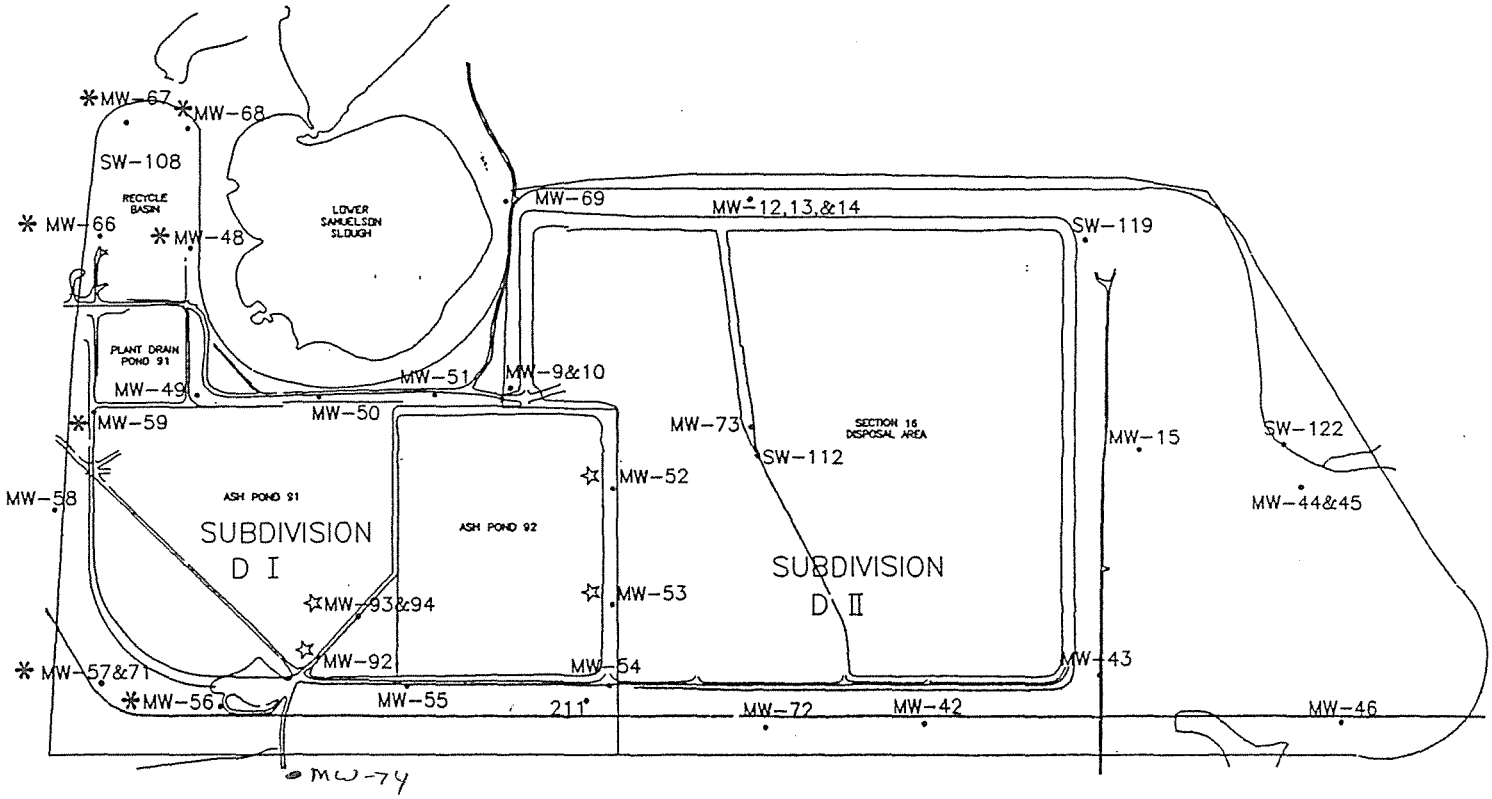

FIGURE 25. Subdivisions DI and DII Water Quality Monitoring Locations

The significance of the information provided above is that the monitoring wells around these ponds have been impacted from different directions (radial ground water flow from the various intermittently active ponds) at different times. This makes trend analysis of historical data a difficult task. These conditions apply to analysis of both Subdivisions DI and DII (discussed in the next section).

Qualitative Discussion of Historical Water Quality Data

Time series data plots of the reportable parameter concentrations for the planned water quality monitoring locations in Subdivision DI are provided in this section. Table 6 provides a summary of the most recent measured concentrations for Subdivision DI in comparison to the water quality guidelines.

Monitoring of all wells in this subdivision except downgradient well MW-10 and additional downgradient well MW-9 began in late 1988. Wells MW-9 and MW-10 have been monitored since 1979. The following sections provide qualitative descriptions of water quality in the subdivision, based on an examination of water quality trends for the various monitoring wells and knowledge of the historical usage of the evaporation ponds within this subdivision.

Upgradient Wells

Upgradient wells MW-57, MW-71 and MW-74 (Figure 26) document ambient conditions and show no obvious trends in the reportable parameters during the period of record. Wells MW-57 (shallow) and MW-71 (deep) are nested at the same location, with MW-71 completed approximately 13 feet below MW-57. Well MW-74 is completed at a depth of 41 feet.

Strontium has consistently been above the water quality guideline of 0.05 mg/l at all three of the upgradient wells throughout the brief period of record. Sulfate has consistently been above the water quality guideline of 250 mg/l at upgradient well MW-74 during the period of record.

Downgradient Wells

Downgradient wells in this subdivision include MW-10, MW-40, MW-50 , and MW-54 (Figures 27 and 28). Monitoring well MW-10 provides the most lengthy period of record for the downgradient wells in this subdivision. Elevated concentrations of chloride and sulfate were evident at well MW-10 almost immediately after the South Ash Pond was placed into service in 1979. Sulfate concentrations have remained elevated, but relatively constant. Chloride concentrations increased sharply at MW-10 in 1988. Boron concentrations in MW-10 show a similar trend to chloride, but with a delayed initial concentration increase. Decreasing concentrations of boron, chloride and sulfate suggest that pond repairs, which began in 1989, may be influencing the ground water quality.

Downgradient wells MW-49 and MW-50, which are directly downgradient of the ash ponds, have generally exhibited similar ground water quality responses. These two wells have exhibited slowly increasing concentrations of boron and chloride, and fairly stable concentrations of strontium and sulfate during the period of record. Well MW-54, which is somewhat more lateral (though still considered downgradient) to the ash ponds, has exhibited more stable concentrations of these four parameters, although the chloride, strontium and sulfate concentrations have consistently been higher than at wells MW-49 and MW-50, which are more directly downgradient of Ash Pond #91. In addition, an elevated concentration of selenium was detected at well MW-54 in 1993, but has essentially not been detected at the other upgradient or downgradient wells in recent years.

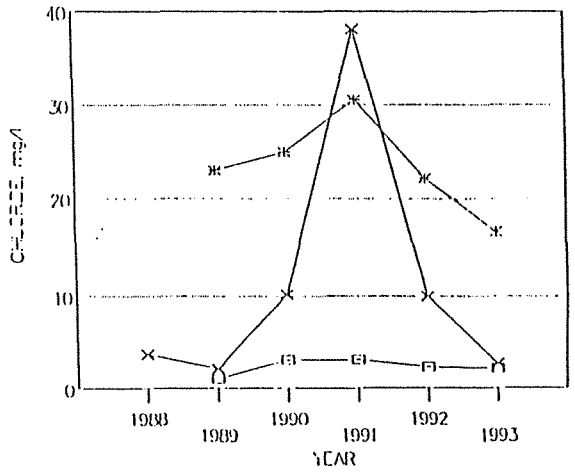

FIGURE 26. # WATER QUALITY TREND CHARTS

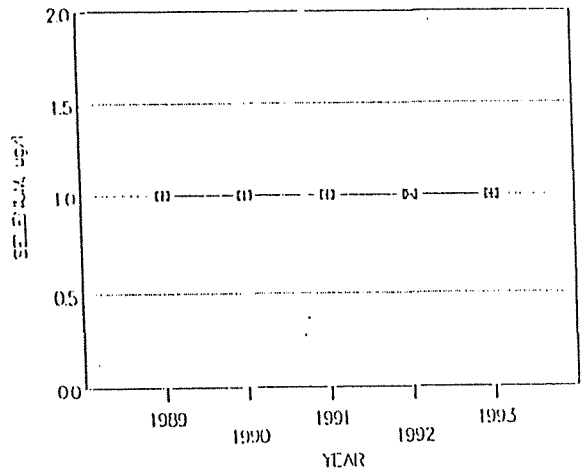
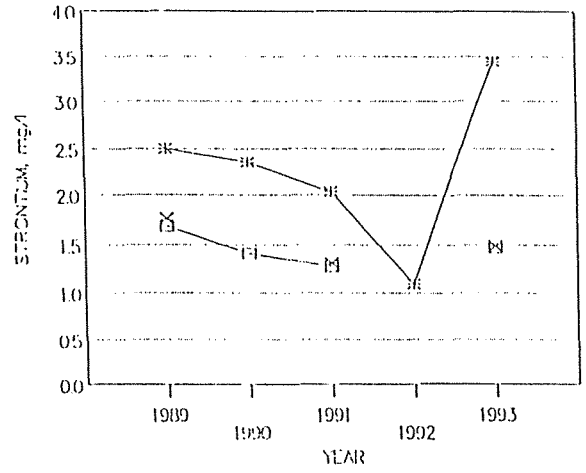
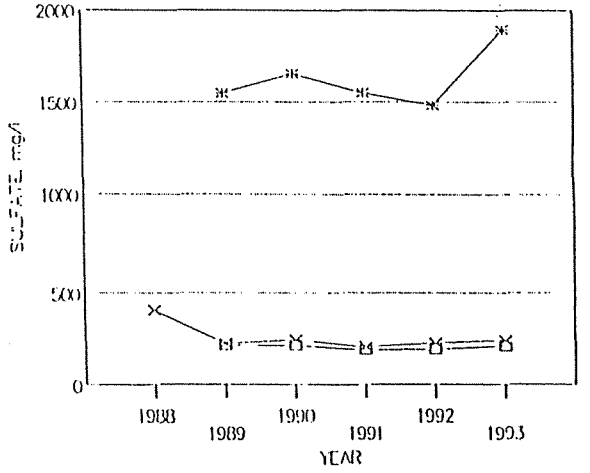
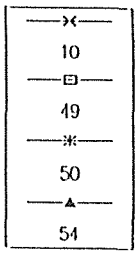
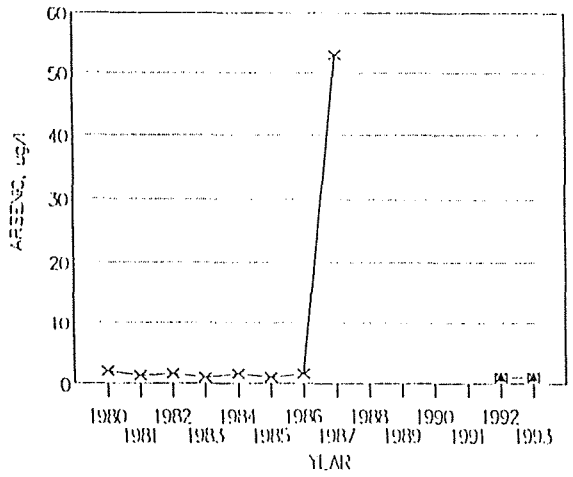


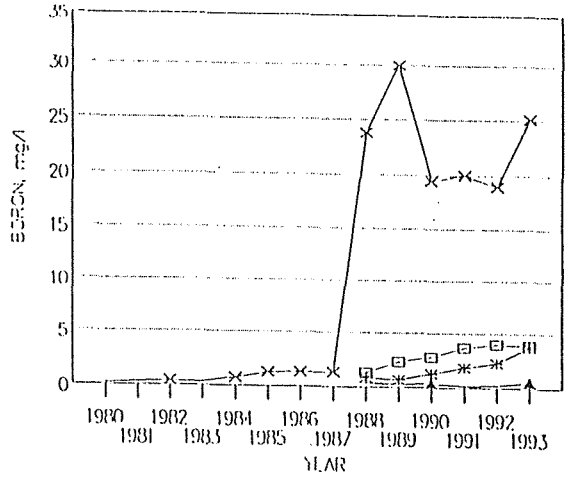
SUBDIVISION DI UPGRADIENT WELLS











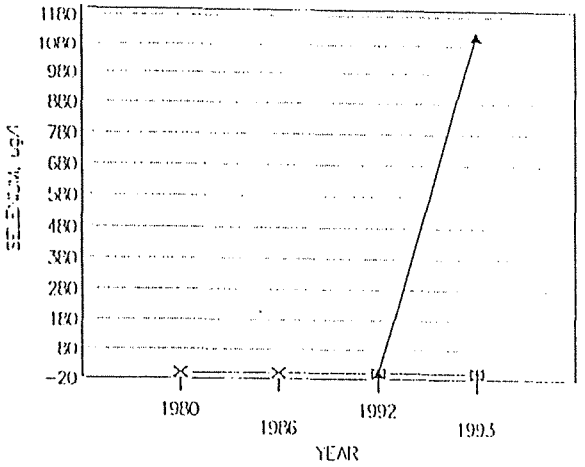


FIGURE 27. WATER QUALITY TREND CHARTS

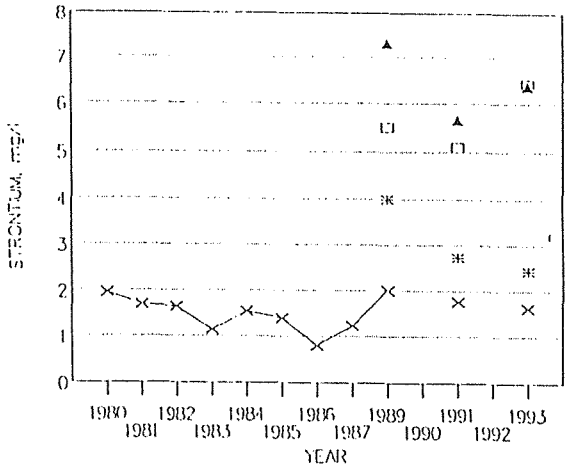
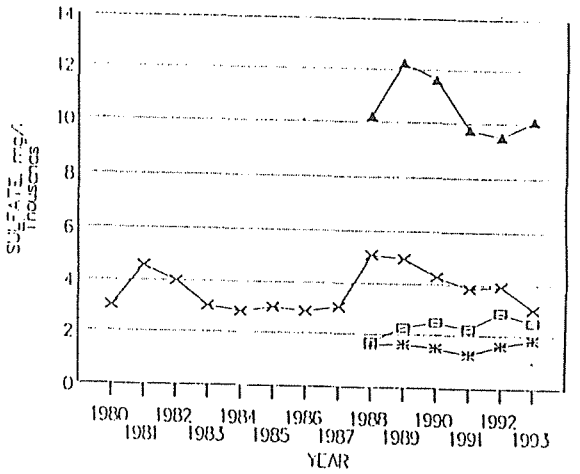


SUBDIVISION DI DOWNGRADIENT WELLS



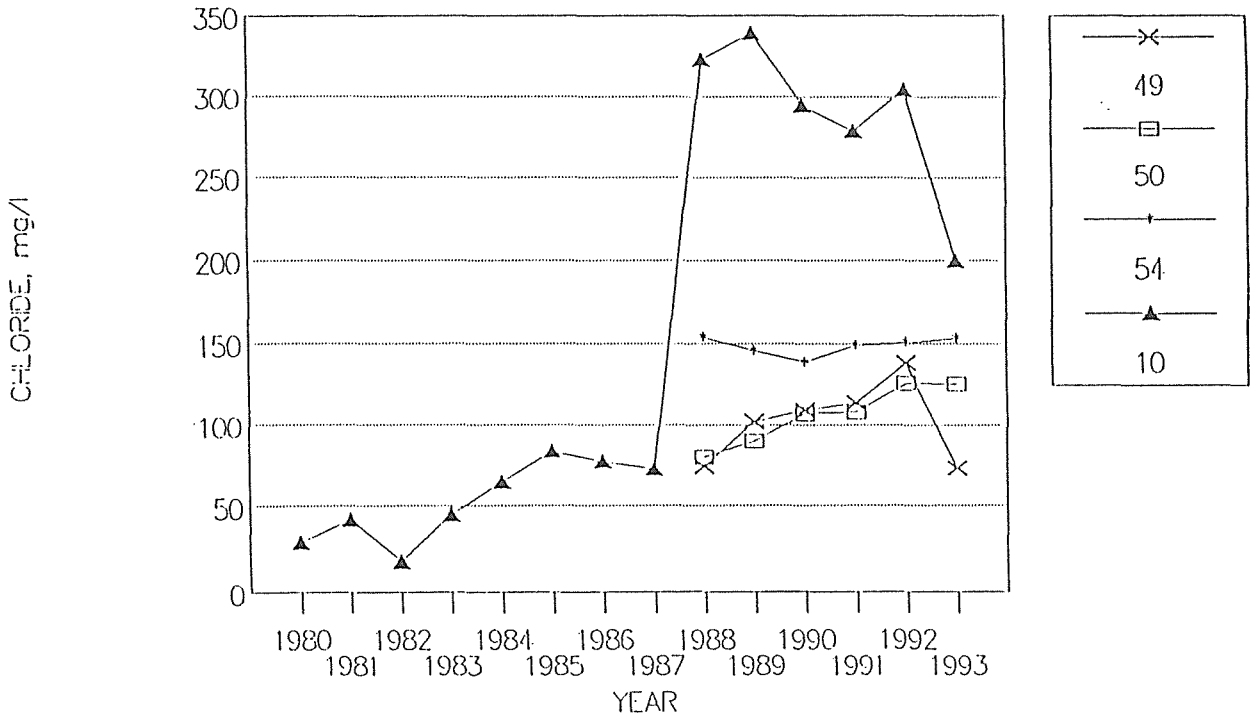


FIGURE 28. WATER QUALITY TREND CHART

SUBDIVISION DI DOWNGRADIENT WELLS

Boron has typically exceeded the water quality guideline of 0.75 mg/l at downgradient wells MW-10, MW-49 and MW-50. The chloride guideline of 250 mg/l has only been exceeded at well MW-10. The elevated selenium concentration (1.11 mg/l) at well MW-54 in August 1993 is the only exceedance in this subdivision of the water quality guideline (0.01 mg/l) for this parameter. Strontium concentrations exceed the water quality guideline of 0.05 mg/l at all downgradient monitoring wells. Sulfate concentrations exceed the water quality guideline of 250 mg/l at all downgradient monitoring wells, with well MW-54 exhibiting the highest concentrations.

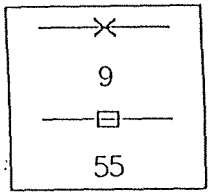
Additional Wells

Additional well MW-9 (Figure 29), which is the deeper well (completed at 53 feet) nested with downgradient well MW-10 (completed at 25 feet), is obviously a downgradient well in this subdivision. Additional well MW-55 (Figure 29), completed at 18.5 feet, is generally considered upgradient based on it's location relative to the northeasterly ground water flow direction in the subdivision. However, well MW-55 could also be considered downgradient, because of likely susceptibility to localized radial ground water flow from Ash Ponds #91 and #92.

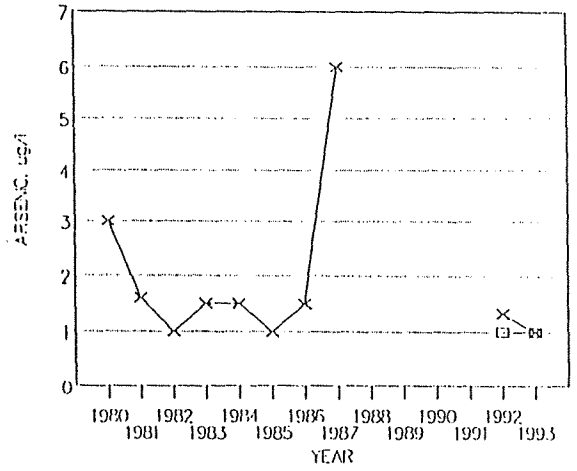
Well MW-9 exhibits very stable water quality trends over it's lengthy period of record. This indicates that there is very little or no influence of the pond operations at this depth (53 feet) of the aquifer, although the shallow well (MW-10) nested at this location exhibited obvious impacts. Although no impacts appear to be evident at well MW-9, boron and sulfate concentrations are consistently close to their respective water quality guidelines of 0.75 mg/l and 250 mg/l. This indicates that the typical background (although well MW-9 is downgradient) concentrations may approximate the water quality guidelines for boron and sulfate. In addition, the strontium concentrations at well MW-9 are consistently above the water quality guideline of 0.05 mg/l. This may indicate that the typical background concentration of strontium may exceed the water quality guideline.

Exceedances of the strontium and sulfate water quality guidelines during the brief period of record are more apparent at additional upgradient well MW-55. However, as indicated above, well MW-55 may be influenced by radial flow away from the ash ponds.

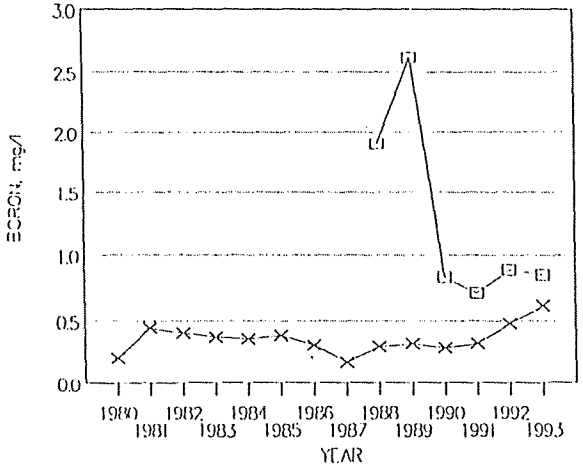
Surface Water



Surface water monitoring locations in this subdivision include SW-108, SW-126, and SW-127 (Figures 30 and 31). The Recycle Pond (SW-108) has been permanently removed from service and will no longer be monitored. South Ash Pond #91 (SW-126) and South Ash Pond #92 (SW-127) have been reconstructed and will continue to be monitored. The two ash ponds receive ash from the plant using a water sluicing method. Part of the water is recycled for reuse and part of the water is piped to the evaporation ponds. The water quality concentrations in these ponds are dependent upon operational conditions.



Influence of Pond Repairs



As indicated above, the complex operational history of the various ponds within this subdivision, combined with the generally brief period of record for most of the wells, makes it difficult to observe the specific influence of pond repairs on ground water quality. However, decreasing concentrations of boron, chloride and sulfate, following significant increases in these parameters, suggest that pond repairs, which began in 1989, may be influencing the ground water quality.

Statistical Analysis

Use of Historical Monitoring Data

The discussion above, along with examination of the water quality data plots for this subdivision, provide a basis for evaluating the water quality conditions at the monitoring locations. Additional data plots in Appendix E include various exploratory statistical methods to assist in determining the applicability of statistical analyses to the data.

As described previously, ground water conditions within this subdivision and Subdivision DII should exhibit complex behavior because of many possible impacts from surrounding areas and changes in usage of the various ponds over time.

Selection of a Statistical Test

Selection of a statistical test to analyze the data in this subdivision is based on the following objectives:

- Identification of recent trends
- Verification of the stability of conditions in upgradient wells
- Characterization of changes in conditions at downgradient wells MW-9 and MW-10
- Comparison of average concentrations in wells having a short period of record with concentrations in upgradient wells

The least-squares regression, as described in Section 1 of Appendix D, is useful in identifying recent trends. As shown in the statistical graphics plots in Appendix E, the regression identifies significant upward linear trends in boron and chloride concentrations at downgradient wells MW-49 and MW-50 using the nine semiannual results spanning the period of record from late 1987 through 1992. The same technique, by failing to identify any significant trends in any of the four upgradient wells, serves to verify the stability of upgradient conditions.

Some changes in downgradient well MW-10 are readily apparent in the time-series plots. Concentrations of boron and chloride increased by an order of magnitude during the first half of 1988. At the same time, sulfate concentrations increased, but remained within the control chart interval ("in control") for sulfate at this well, as indicated in the statistical graphics plot in Appendix E. Concentrations of boron, chloride and sulfate peaked in 1989 at well MW-10 and have been slowly decreasing since. Ongoing statistical tests of recent conditions should, therefore, use data beginning in 1990, but no earlier.

Concentrations of reportable parameters in additional downgradient well MW-9 (deep well nested with shallow well MW-10) have generally been comparable to, or lower than, those in upgradient wells. The control charts begun in 1980 are an appropriate method to continue testing results at this well.

To compare downgradient concentrations with upgradient concentrations, the spatial variability of conditions in upgradient wells must be accounted for. To do this tolerance or prediction intervals were developed for the mean concentrations of the reportable parameters. This technique, described below, was applied separately to each reportable parameter. It uses the variation of average concentrations among the upgradient wells to project limits on average concentrations which can be expected in other wells. The average concentrations at the downgradient wells are then compared to these limits. Downgradient wells with average concentrations outside these limits should be considered significantly changed. This method overcomes the difficulty of having no historical background for the downgradient wells to characterize conditions before the ground water may have been affected by the facility.

Methods and Calculations

Section 3 of Appendix D describes the calculations for tolerance limits and how tolerance limits are applied to screen average concentrations at downgradient wells. Tolerance limits were not calculated for arsenic or selenium due to the large number of non-detects during the period of record. All values are in units of mg/l.

Error Rates

Error rates for the procedures recommended here are discussed in the Appendices. See also the error rates section in the Subdivision A analysis.

Discussion

A tolerance limit developed from a small (sample size [N] less than 10) number of upgradient wells will be three or more standard deviations above the average concentrations observed in the wells. This often leads to extraordinarily high limits which are not useful for screening additional wells when small changes in concentration must be detected. However, in the event that the average concentration at a downgradient well exceeds an upgradient-based tolerance limit, then one can be confident that conditions at that well are significantly elevated.

Portions of the following discussion are applicable to Subdivisions DI and DII, since Subdivision DII utilizes the same upgradient wells as Subdivision DI. For application of the tolerance limit method to Subdivisions DI and DII several choices of upgradient well combinations are available. Three wells (MW-57, MW-71 and MW-74) are designated as upgradient for Subdivision DI. The same three wells are designated as upgradient for Subdivision DII. One additional well (MW-55) is considered upgradient in Subdivision DI, and one additional well (MW-72) is considered upgradient in Subdivision DII.

To illustrate the effect of choice of upgradient wells, we have computed tolerance limits based on three such choices:

- 3 Wells: Upgradient wells MW-57, MW-71, and MW-74 (all from Subdivision DI)
- 4 Wells: Upgradient wells MW-57, MW-71, MW-74; Additional well MW-55 (all from Subdivision DI)
- 5 Wells: Upgradient wells MW-57, MW-71, MW-74; Additional wells MW-55 and MW-72 (includes additional upgradient well MW-72 from Subdivision DII)

Table 7 presents the calculated tolerance limits for the four reportable parameters consistently detected in wells within Subdivisions DI and DII.

Tolerance limits generally decrease with increasing numbers of upgradient wells, because the uncertainty in the spatial distribution of average concentrations decreases. Tolerance limits based on five upgradient wells provide an effective screening procedure for identifying changes in ground water quality conditions. The following observations and interpretations can be made by examining the water quality trend charts and comparing approximate average concentrations at monitoring locations to the tolerance limits based on a sample size of five calculated above.

TABLE 7

CALCULATED TOLERANCE LEVELS - SUBDIVISIONS DI AND DII

Parameter	Mean (mg/l)	Standard Deviation (mg/l)	Sample Size	ANOVA P-Value	Tolerance Limit (mg/l)
Boron	0.44	0.76	3	0.00 %	6.26
Boron	0.70	1.47	4	0.08 %	8.28
Boron	0.57	1.44	5	0.01 %	6.61
Chloride	14.3	28.3	3	9.03 %	230.6
Chloride	17.9	31.0	4	1.03 %	177.1

Strontium	1.80	0.97	4	0.02 %	6.77
Strontium	1.58	1.35	5	0.00 %	7.23
Sulfate	681	1,854	3	0.00 %	14,874
Sulfate	976	2,311	4	0.00 %	12,863
Sulfate	827	2,138	5	0.00 %	9,814

Notes: Mean is the mean value of the average background concentrations. Standard Deviation is the standard deviation of the average background concentrations. Sample size is the number of upgradient wells used. ANOVA P-Value is the Analysis of Variance P-Value used to estimate the average concentrations and standard deviation of the averages; the very low values confirm the significance of the assumption of spatial variability. Tolerance Limit is the one-sided upper 95%-coverage, 95%-confidence tolerance limit.

- The sudden increases in boron and chloride concentrations at downgradient well MW-10 in 1988 have resulted in average concentrations computed since that time that are above the calculated tolerance limits for those parameters.

- Average strontium concentrations in downgradient well MW-54 are about 6.5 mg/l, which is below the calculated tolerance limit of 7.23 mg/l.

- Average sulfate concentrations in downgradient well MW-54 exceed the sulfate tolerance limit; however, the last four sample measurements have oscillated above and below the tolerance limit.

- Average chloride concentrations in downgradient well MW-54 exceed the chloride tolerance limit; however, the individual sample measurements have oscillated marginally above and below the tolerance limit throughout the period of record.

- Average concentrations of boron, chloride, strontium, and sulfate in downgradient wells MW-49 and MW-50 do not exceed their respective tolerance limits.

Conclusions which can be drawn from the statistical analysis are:

- Downgradient well MW-54 has been adversely impacted by chloride and sulfate, and probably by strontium.

- Downgradient wells MW-49 and MW-50 may not have been impacted, but are showing indications (based on the significant regression slopes for boron and chloride indicated on the plots in Appendix E) of long-term, low-level adverse effects.

SUBDIVISION DII

This subdivision, located in the southeast section of the site (Figure 25), encompasses the Section 16 Disposal Area. There are no separate upgradient wells specified for this subdivision because of its location with respect to Subdivision DI. The upgradient wells used for Subdivision DI are also used as upgradient wells for this subdivision. Water quality sampling locations (with completion depths below ground surface for monitoring wells) in this subdivision and reported herein are as follows:

Ground Water

Upgradient	**Downgradient**	**Additional**
MW-57 (32.7 ft)	MW-14 (20 ft)	MW-12 (78 ft) [Downgradient]
MW-71 (45.5 ft)	MW-15 (20 ft)	MW-13 (55 ft) [Downgradient]
MW-74 (41 ft)	MW-42 (14.4 ft)	MW-72 (24 ft) [Upgradient]
	MW-43 (14.6 ft)	MW-73 (28 ft) [Downgradient]

Local ground water flow direction in this subdivision is generally toward the east, with possibly, some localized northeast and southeasterly flow components in the eastern portion of the Section 16 Disposal Area.

Surface Water

None

The discussion in the previous section, regarding usage of the Subdivision DI ash ponds and the Subdivision DII Section 16 Disposal Area, applies to this subdivision. The test selection, methods, and error rates remain the same.

Qualitative Discussion of Historical Water Quality Data

Time series data plots of the reportable parameter concentrations for the planned water quality monitoring locations in Subdivision DII are provided in this section. Table 8 provides a summary of the most recent measured concentrations for Subdivision DII in comparison to the water quality guidelines.

Downgradient wells MW-14 and MW-15 and additional wells MW-12 and MW-13 have been monitored since 1979. The other wells in the subdivision have generally been monitored since either 1986 or 1988. The following sections provide qualitative descriptions of water quality in the subdivision, based on an examination of water quality trends for the various monitoring wells and knowledge of the historical usage of the evaporation ponds within this subdivision.

Upgradient Wells

Because Subdivisions DI and DII utilize the same upgradient wells (MW-57, MW-71 and MW-74 - Figure 26), the discussion of upgradient wells in this subdivision is identical to the discussion in the previous section for Subdivision DI.

Upgradient wells MW-57, MW-71 and MW-74 document ambient conditions and show no obvious trends in the reportable parameters during the period of record. Wells MW-57 (shallow) and MW-71 (deep) are nested at the same location, with MW-71 completed approximately 13 feet below MW-57. Well MW-74 is completed at a depth of 41 feet.

Strontium has consistently been above the water quality guideline of 0.05 mg/l at all three of the upgradient wells throughout the brief period of record. Sulfate has consistently been above the water quality guideline of 250 mg/l at upgradient well MW-74 during the period of record.

Downgradient Wells

Downgradient wells in this subdivision include MW-14, MW-15, MW-42, and MW-43 (Figure 32). Monitoring wells MW-14 and MW-15, which are both shallow, provide the most lengthy period of record for the downgradient wells in this subdivision. Concentrations of boron, chloride, strontium, and sulfate began increasing at both of these wells during the period from 1980 to 1982. Obvious increases continued through the period 1986 to 1991, depending upon the specific well and parameter. At the other downgradient wells (MW-42 and MW-43), which are also both shallow, the concentrations of all reportable parameters have remained fairly consistent during the period of record, with the exception of sulfate at well MW-43, which has exhibited a general decrease since 1986.

Boron has typically exceeded the water quality guideline of 0.75 mg/l at all four downgradient wells in this subdivision. The chloride guideline of 250 mg/l has historically only been exceeded at wells MW-14 and MW-15; however, in recent years the concentrations have been declining, such that chloride at well MW-15 was below the guideline during 1993. Strontium concentrations exceed the water quality guideline of 0.05 mg/l at all downgradient monitoring wells, but have generally been decreasing at wells MW-14 and MW-15 since approximately 1986. Sulfate concentrations exceed the water quality guideline of 250 mg/l at all downgradient monitoring wells, but have generally been decreasing in recent years at wells MW-14, MW-15 and MW-43.

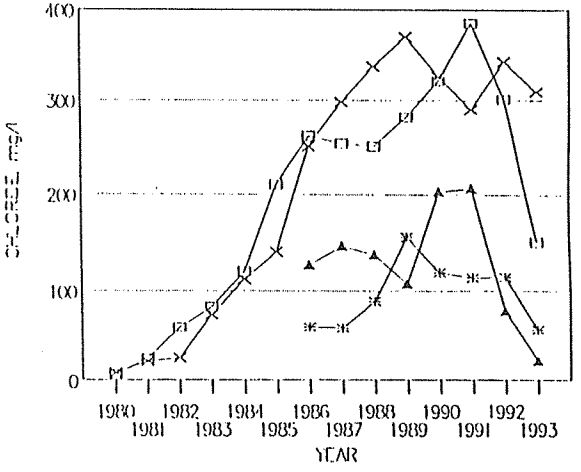

FIGURE 32. WATER QUALITY TREND CHARTS

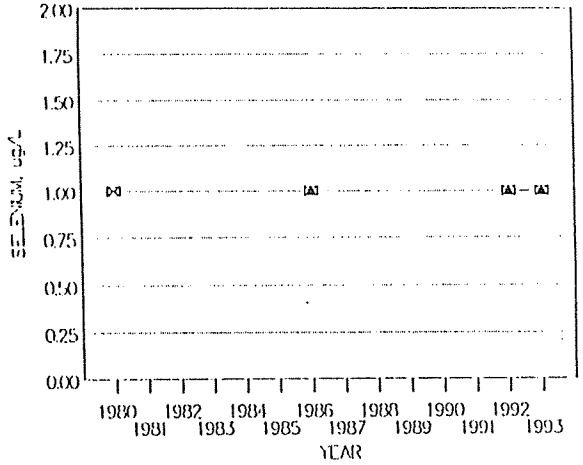
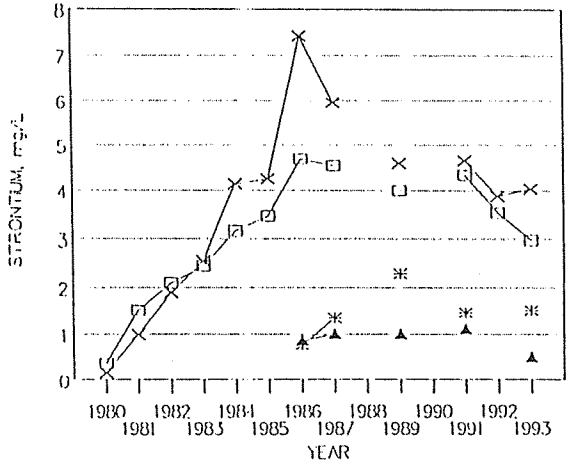
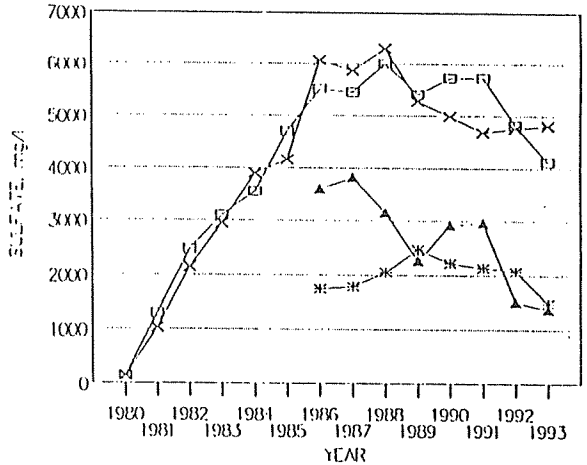


SUBDIVISION DII DOWNGRADIENT WELLS





Additional Wells

Additional wells in this subdivision include MW-12, MW-13, MW-72, and MW-73 (Figure 33). Additional wells MW-12 (completed at 78 feet) and MW-13 (completed at 55 feet), are deep wells nested with downgradient well MW-14 (completed at 20 feet). Additional well MW-72 (completed at 24 feet) is considered upgradient based on it's location relative to the easterly ground water flow direction in the subdivision. Additional well MW-73 is downgradient, based upon it's location on a dike in the middle of the Section 16 disposal area.

Additional downgradient wells MW-12 and MW-13 exhibit stable water quality trends over their lengthy periods of record, with the deeper well (MW-12) showing the greatest stability. This indicates that there is very little or no influence of the pond operations at the depth (78 feet) of completion of well MW-12, although the shallow well (MW-14) nested at this location exhibited obvious impacts. Additional upgradient well MW-72 has also exhibited stable concentrations during it's short period of record. Additional downgradient well MW-73, which is completed shallow, has exhibited elevated boron, chloride, strontium, and sulfate concentrations during it's short period of record.

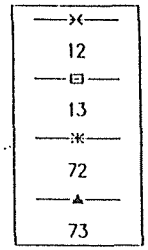
Additional deep downgradient well MW-12 does not appear to exhibit impacts due to site operations; however, the strontium concentrations at that well are consistently above the water quality guideline of 0.05 mg/l. This may indicate that the typical background concentration of strontium may exceed the water quality guideline. Strontium and sulfate exceeded their respective water quality guidelines of 0.05 mg/l and 250 mg/l at the mid-depth downgradient well, MW-13, which is nested with MW-12 and MW-14. Additional upgradient well MW-72 has exceeded the water quality guideline for strontium throughout it's short period of record. Additional downgradient well MW-73 exceeds the water quality guidelines for boron, chloride, strontium, and sulfate.

Influence of Pond Repairs

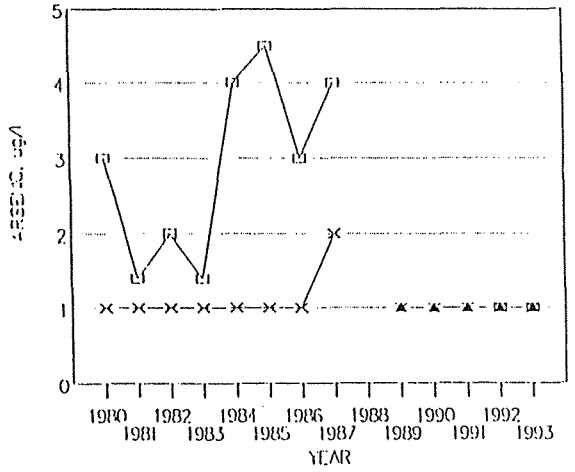
As indicated previously in the discussion of Subdivision DI, the complex operational history of the various ponds within this subdivision and adjacent Subdivision DI, combined with the generally brief period of record for most of the wells, makes it difficult to observe the specific influence of pond repairs on ground water quality.

Statistical Analysis

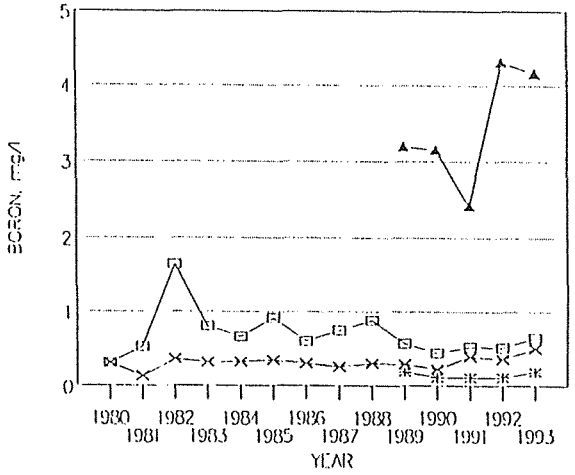
Use of Historical Monitoring Data



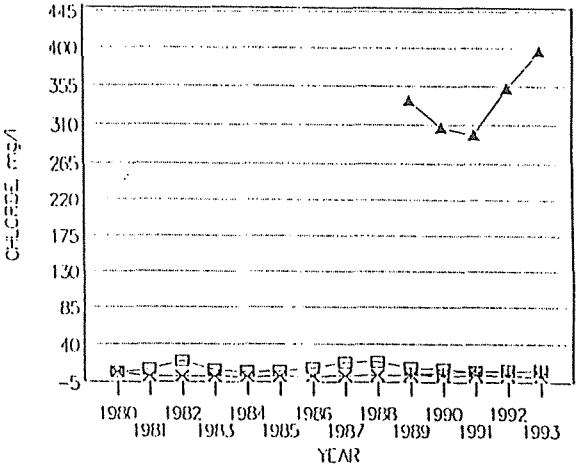
The discussion above, along with examination of the water quality data plots for this subdivision, provide a basis for evaluating the water quality conditions at the monitoring locations. Additional data plots in Appendix E include various exploratory statistical methods to assist in determining the applicability of statistical analyses to the data.



As described previously, ground water conditions within this subdivision and Subdivision DI should exhibit complex behavior because of many possible impacts from surrounding areas and changes in usage of the various ponds over time.



Selection of a Statistical Test



See Subdivision DI for a discussion of the appropriate statistical tests for this subdivision.

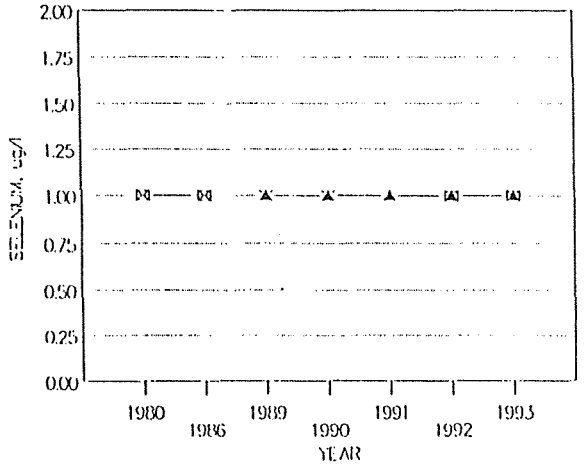


FIGURE 33. WATER QUALITY TREND CHARTS
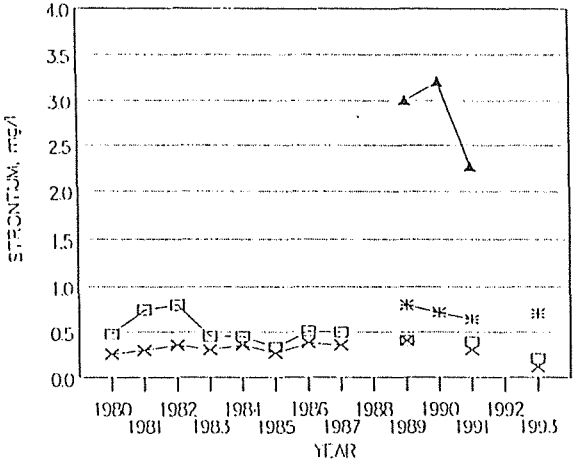
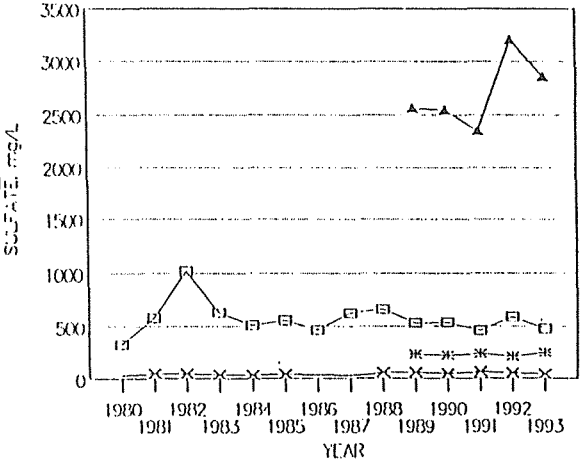
SUBDIVISION DII ADDITIONAL WELLS





Methods and Calculations

Table 7 in the previous section (Subdivision DI) provides a summary of the calculated tolerance limits applicable to Subdivisions DI and DII. Section 3 of Appendix D describes the calculations for tolerance limits and how tolerance limits are applied to screen average concentrations at downgradient wells. Tolerance limits were not calculated for arsenic or selenium due to the large number of non-detects during the period of record. All values are in units of mg/l.

Error Rates

Error rates for the procedures recommended here are discussed in the Appendices and in the error rates section in the Subdivision A analysis.

Discussion

In general, much of the discussion regarding application of tolerance limits to Subdivision DI and DII data, provided in the previous section, is applicable here. Downgradient wells MW-14 and MW-15 in this subdivision are analogous to well MW-10 in Subdivision DI. Between late 1980 and mid-1986 wells MW-14 and MW-15 exhibited consistent linear increases in concentrations of boron, chloride, strontium, and sulfate (see trend charts). Since 1986, these concentrations have slightly decreased or remained approximately steady.

Relative to wells MW-14 and MW-15, conditions in downgradient wells MW-42 and MW-43 appear stable and low. However, compared to the history of concentrations in the upgradient wells, concentrations of boron, chloride and sulfate in these wells have been significantly more variable. There are many tests of difference in variability. One rule of thumb is that a ratio of 3:1 or greater in standard deviations is significant. Using the range of data as a simple, surrogate measure of variability, one can see ratios of 5:1 or 10:1 in ranges, parameter by parameter, when comparing downgradient wells MW-42 or MW-43 with data in upgradient wells MW-57, MW-71 or MW-74.

It is unclear how significantly increased variability relates to impacts to ground water quality. However, using the tolerance limits for Subdivisions DI and DII developed in the previous section, it can be seen that average boron concentrations in downgradient wells MW-42 and MW-43 of about 10 mg/l (Figure 32) exceed the calculated tolerance limit of 6.61 mg/l. Therefore, some impact has probably occurred, however, the tendency toward lower values in 1992 and 1993 is a sign of possible improvement.

Finally, average chloride concentrations in additional downgradient well MW-73 (Figure 33) exceed the tolerance limit of 138 mg/l. Average concentrations of the other reportable parameters at this well fall within the tolerance limits calculated from the upgradient wells.

SUBDIVISION E

This subdivision spreads over the entire site and at some points beyond the site (Figure 34). No upgradient or downgradient wells have been designated in this area because they could be influenced by more than one source. Water quality sampling locations (with completion depths below ground surface for monitoring wells) in this subdivision and reported herein are as follows:

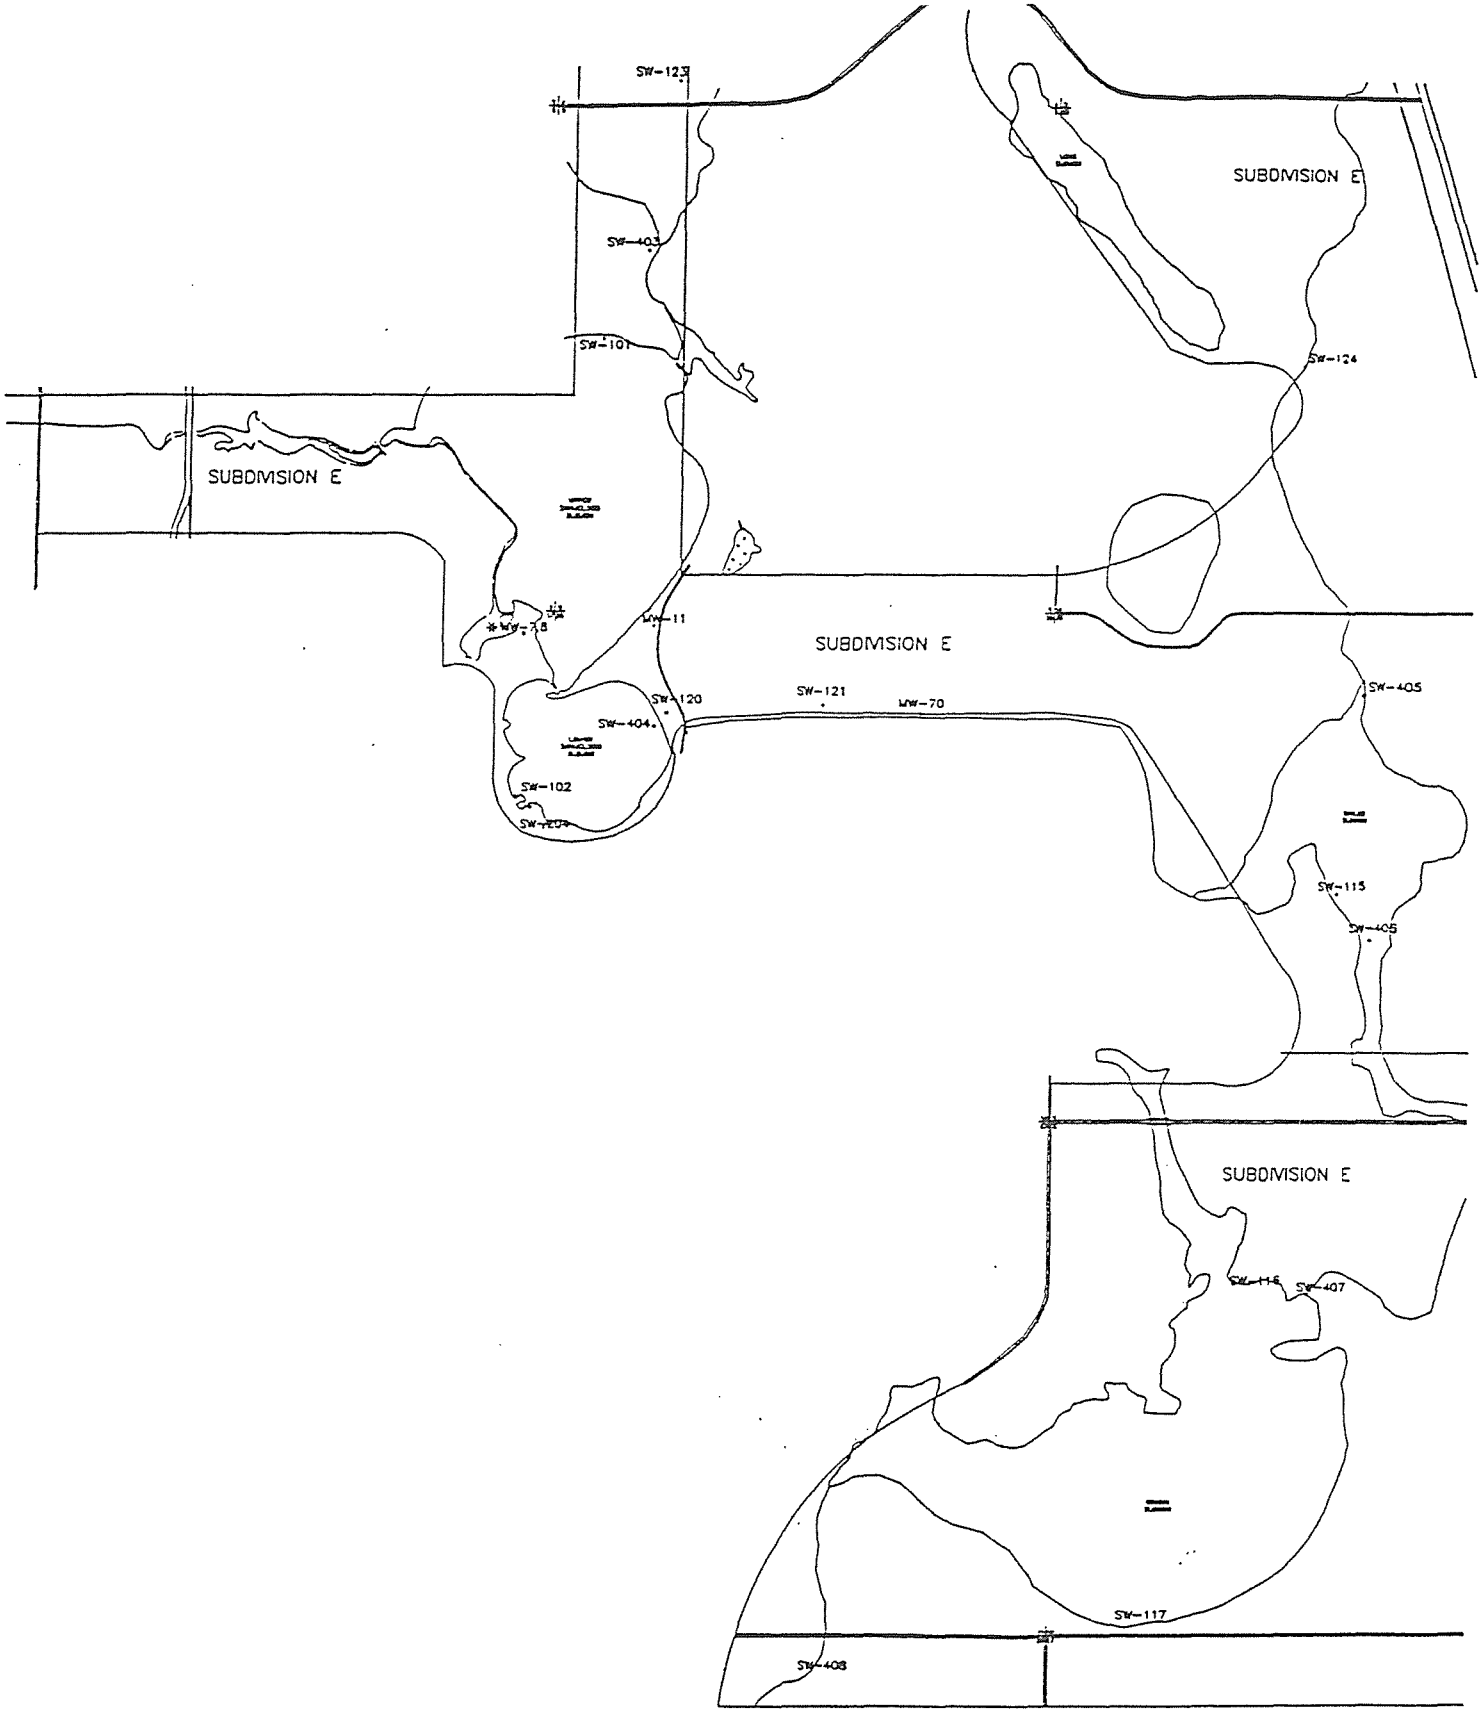


FIGURE 34. Subdivision E Water Quality Monitoring Locations

Ground Water

Upgradient	Downgradient	Additional
None	None	MW-7 (68 ft) MW-8 (20 ft)

Ground water flow direction in this subdivision is variable because the subdivision extends over the entire site.

Surface Water

SW-101
SW-102
SW-103
SW-115
SW-117
SW-123

Wells and sampling locations in this subdivision are associated with the surface water system, which is the shallow ground water discharge point. Ground water from Subdivisions A and B flows southerly toward the surface water bodies. Ground water from Subdivisions C and DI flows northerly toward the same surface water bodies. Ground water from Subdivision DII flows north and east. Additionally, the surface water flows from west to east across most of the site until moving southerly on the east side of the Section 16 Disposal Area.

Qualitative Discussion of Historical Water Quality Data

Time series data plots of the reportable parameter concentrations for the planned water quality monitoring locations in Subdivision E are provided in this section. Table 9 provides a summary of the most recent measured concentrations for Subdivision E in comparison to the water quality guidelines.

Ground Water

Wells associated with this subdivision are additional wells MW-7 (completed at 68 feet) and MW-8 (completed at 20 feet), which form a nested pair (Figure 35). They are situated near the south end of Upper Samuelson Slough, northeast of the Recycle Basin. These wells have a period of record extending from 1979.

Shallow well MW-8 is of special interest because of persistent anomalous elevated concentrations of sulfate (approximately 30,000 to 60,000 mg/l) during the entire period of record. The adjacent nested well (MW-7), which is completed at 68 feet, does not show a similar response. It is thought that the high sulfate concentrations at well MW-8 may be, at least partially, related to a scrubber slurry release which occurred during start-up in 1979. While boron, chloride and strontium concentrations have been quite variable at shallow well MW-8 during most of the period of record, the only constituents which currently exceed the water quality guidelines are strontium at wells MW-7 and MW-8 and sulfate at well MW-8.

Monitoring wells MW-7 and MW-8 were removed in June 1993 in conjunction with reconstruction of Ash Pond #91 and abandonment of the Recycle Basin.

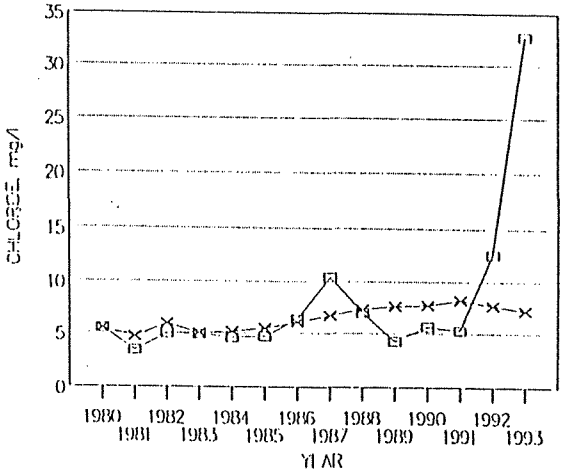

FIGURE 35. WATER QUALITY TREND CHARTS

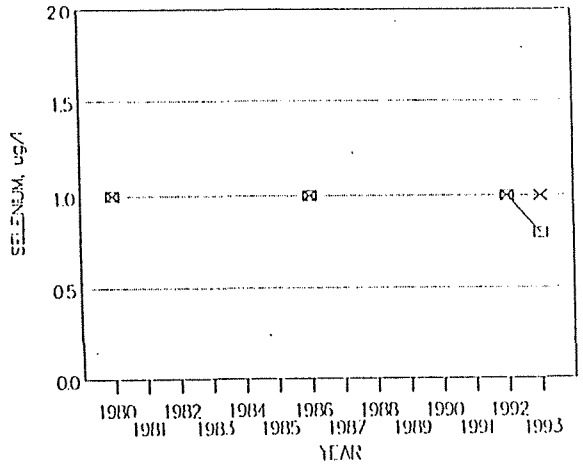
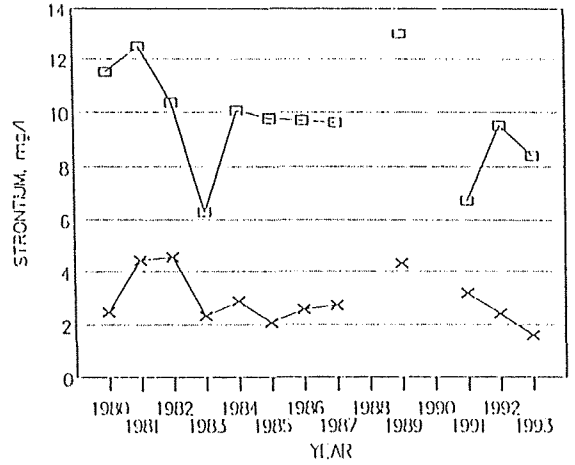
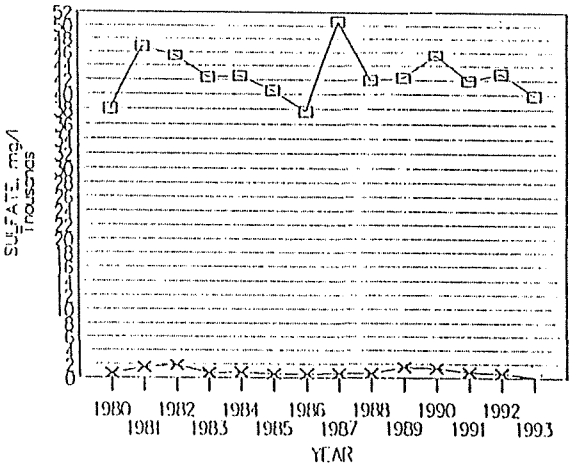


SUBDIVISION E ADDITIONAL WELLS





Surface Water

As described above, the surface water system generally moves from west to east and then southerly. The sequence of sampling locations, from upstream to downstream, is as follows:

Upstream	SW-103 East Weller Slough
	SW-123 Falkirk Mine Drainage
	SW-101 Upper Samuelson Slough
	SW-102 Lower Samuelson Slough
	SW-115 Saylor Slough
Downstream	SW-117 Gradin Slough

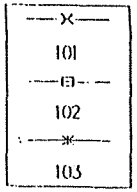
Water quality data plots for these locations are provided in Figures 36 and 37. Elevated concentrations are observed for boron, chloride, strontium, and sulfate. Arsenic and selenium are either not detected or are significantly below their respective water quality guidelines.

Concentrations in the surface waters are affected by pond leakage into the ground water which discharges into the surface water bodies. Concentrations are generally less upstream than downstream. Increased concentrations in the early-1980s as SW-115 and SW-117 are probably a result of the use of the former East Ash Pond and the former South Ash Pond, both of which are now known to have leaked. Influence from the evaporation ponds was not yet apparent during this early operational period. The rapid concentration increase in the early 1990s, especially at SW-101, is probably the cumulative effect of leakage from the four evaporation ponds in the area. The concentrations have shown a dramatic decrease since pond repairs have been made (allowing for lag time of ground water flow from the vicinity of the evaporation ponds to the Upper Samuelson Slough). In general, the elevated concentrations (especially of chloride and sulfate) have decreased since the mid-1990s because of operational changes and the extensive pond repair program.

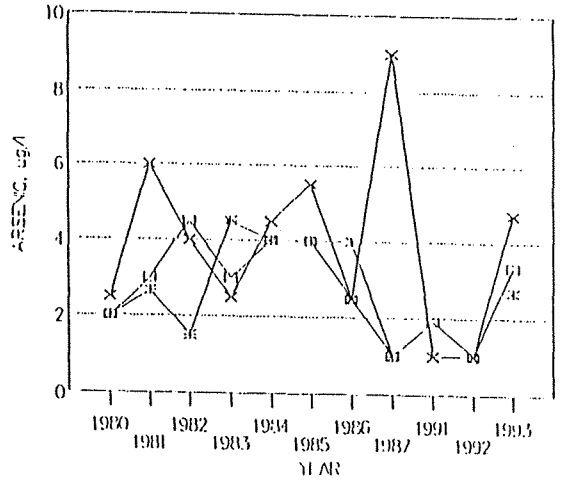
Statistical Analysis

Use of Historical Monitoring Data

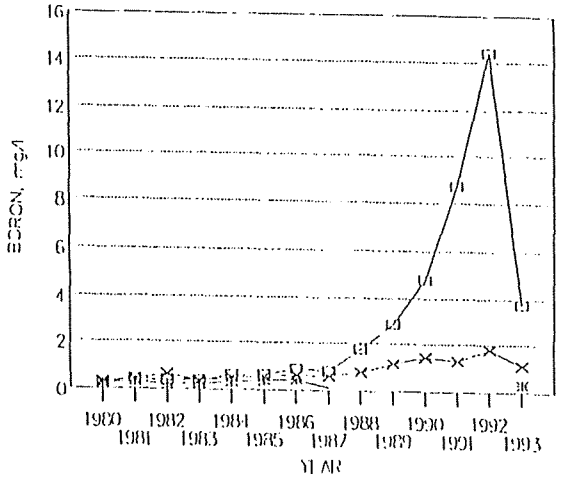
The discussion above, along with examination of the water quality data plots for this subdivision included in this section, provide a basis for evaluating the water quality conditions at the monitoring locations. Additional data plots in Appendix E include various exploratory statistical methods to assist in determining the applicability of statistical analyses to the data.



Significant variability in boron and chloride concentrations is apparent in additional well MW-8; however, the concentrations of both parameters are typically below the water quality guidelines. This variability is taken into account in applying the statistical method for this subdivision.



Selection of a Statistical Test



Because no upgradient wells exist in this subdivision for comparison, statistical tests must be intra-well in nature. The histories of the reportable parameters at each well are stable over time, so that use of control charts is an appropriate statistical method for this subdivision.

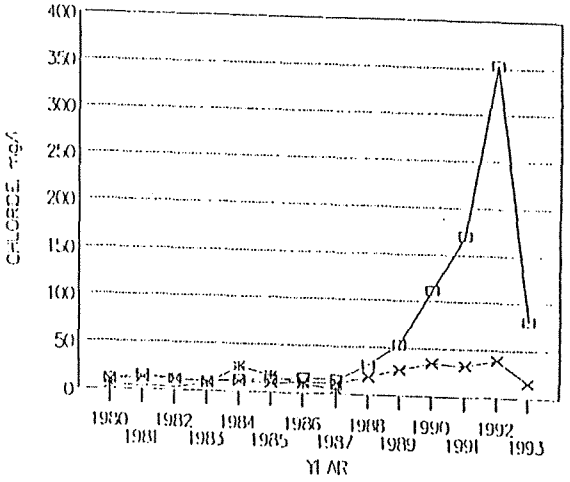


FIGURE 36. WATER QUALITY TREND CHARTS

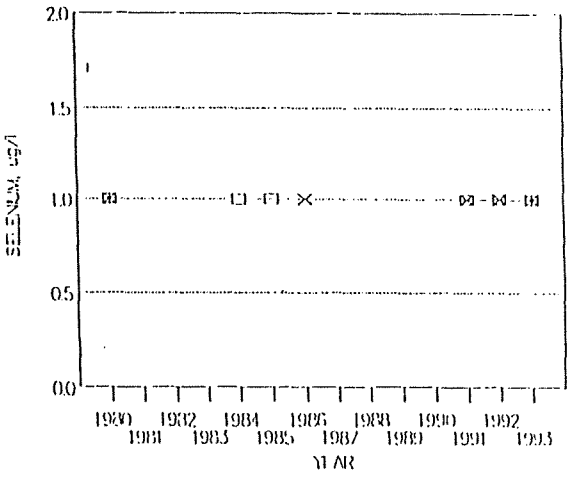
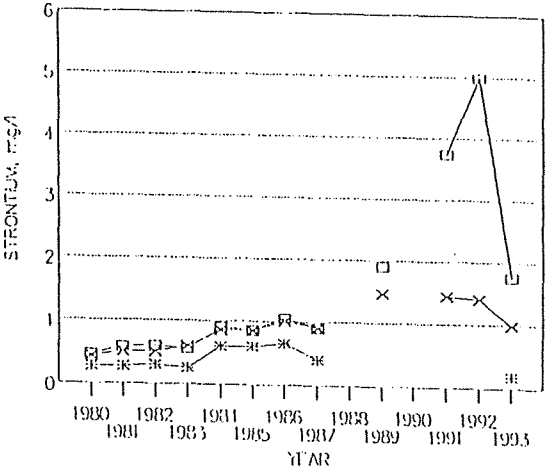
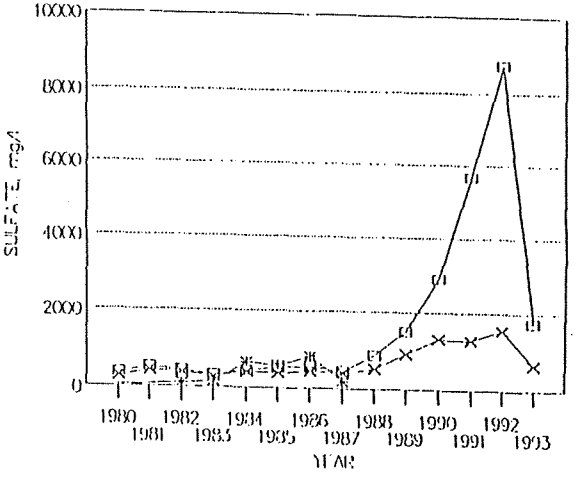
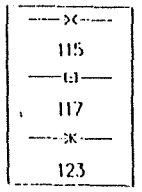
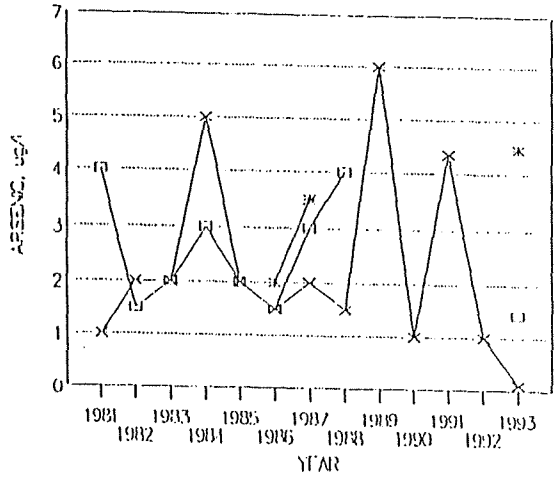


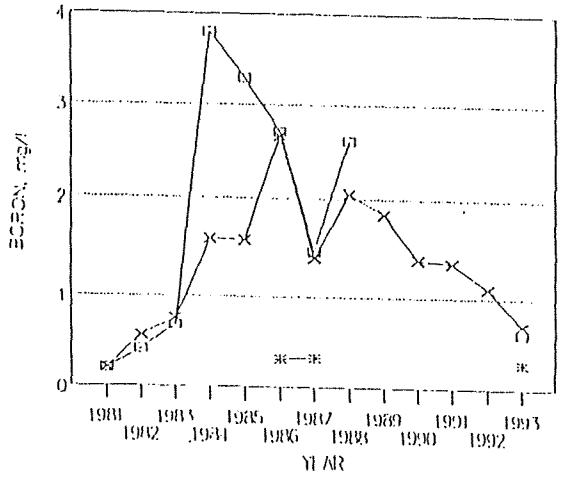
SUBDIVISION E SURFACE WATERS











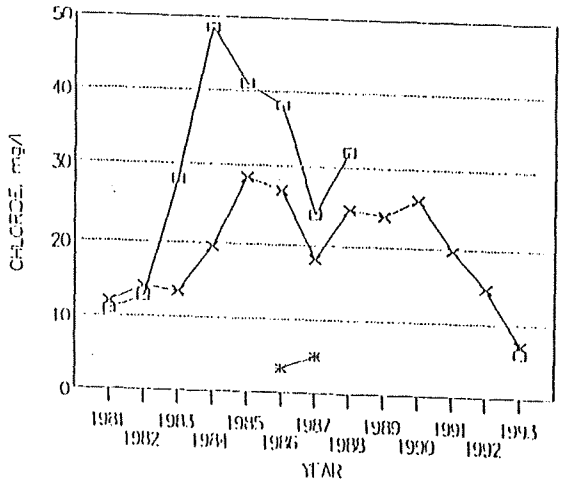


FIGURE 37. WATER QUALITY TREND CHARTS

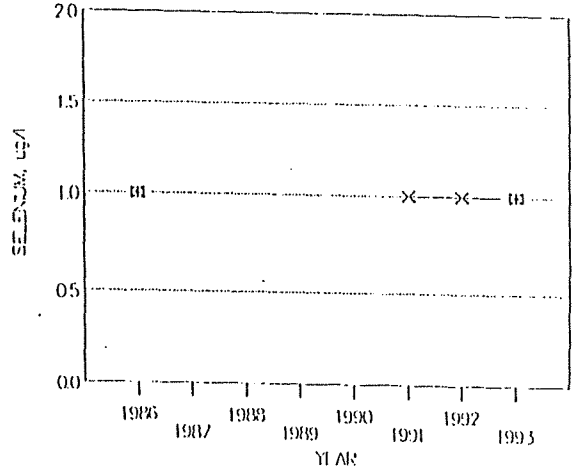
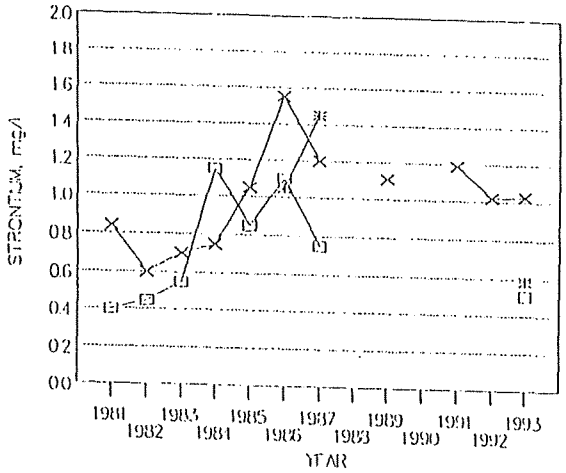
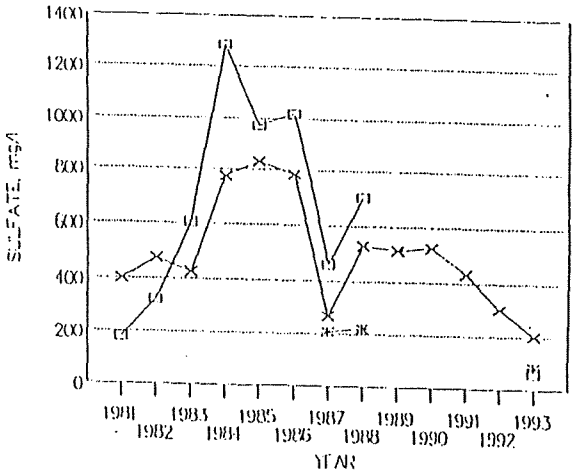


SUBDIVISION E SURFACE WATERS





Methods and Calculations

Section 2 of Appendix D discusses control charting methods and calculations. Because the control chart method requires that the sample data be normally distributed, the variability of the parameter concentrations was assessed prior to application of the method. A probability plot of boron concentrations in well MW-8 indicated that the data are lognormally distributed (i.e., a logarithmic transformation of the data produces a normal distribution of the transformed data). Therefore, control charts for boron at well MW-8 should be based on the logarithms of the concentrations.

Error Rates

Section 2 of Appendix D discusses error rates for control charts.

Discussion

Control charts developed for boron, chloride, strontium, and sulfate at addition wells MW-7 and MW-8 are provided on the figures included in Appendix E. Examination of the control charts indicates that the latest (1993) value of chloride at well MW-8 is outside of the control limits: the running mean is about 5 mg/l, the upper control limit is about 20 mg/l, and this recent measurement is over 32 mg/l. Apart from a high arsenic concentration in 1980, this is the only anomalous value among all the Subdivision E data. Even though the recent elevated chloride value is outside the control limits, the value is far below the water quality guideline of 250 mg/l.

Data in well MW-8 appear to exhibit seasonality. This is difficult to characterize and quantify because monitoring is only semiannual to annual. However, the regular pattern of up and down variations which is exhibited to varying degrees by several reportable parameters (e.g., boron, chloride and sulfate) during their histories is typical of seasonality. This behavior is not unusual for surface water monitoring data or for measurements of conditions strongly affected by surface water, such as at shallow well MW-8. The sizes of the fluctuations relative to average concentrations tend to be small; so they can be considered "noise" in the data.

SUBDIVISION F - SECTIONS 5, 31 AND 32 DISPOSAL AREAS

These three disposal areas are located approximately one mile north of Evaporation Ponds #91 and #92 (Figure 38). The disposal areas in Subdivision F are not used for liquids. These areas are engineered landfills for dewatered ash that has been removed from the former South Ash Pond and from current Ash Ponds #91 and #92. The sites were clay lined before ash was placed into these areas. Water quality sampling locations (with completion depths below ground surface for monitoring wells) in this subdivision are as follows:

Qualitative Discussion of Historical Water Quality Data

Tables 10, 11 and 12 provide a summary of the most recent measured concentrations for Subdivision F (Sections 5, 31, and 32, respectively) in comparison to the water quality guidelines. Water quality trend charts are provided in Figures 39-47.

The Subdivision F disposal areas are in locations that were previously mined for coal. Water quality conditions more likely represent equilibration of post-mining effects rather than impacts from ash disposal. This is especially true at upgradient locations MW-544 and MW-551 (upgradient for Sections 31 and 32, respectively) where weathered "punky" coal was encountered in the Falkirk Mine Area. Elevated constituent concentrations in the Falkirk Mine Area are suspected of being related to contact of the ground water with naturally-occurring weathered coal.

Monitoring wells at each of the three disposal sites are completed in two units at each location. The wells monitor ground water found at approximately the same elevation as the ash and also the first water-bearing unit below the ash disposal facility.

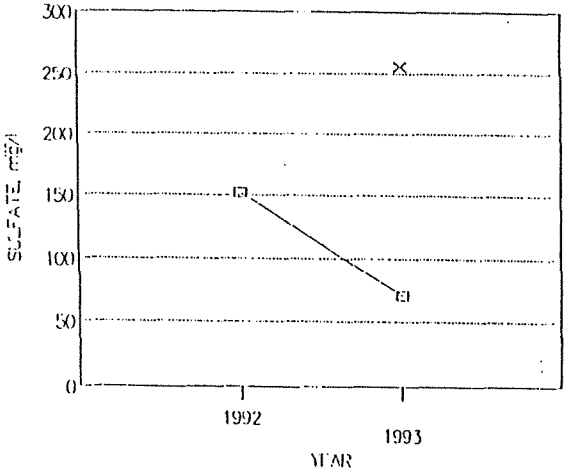

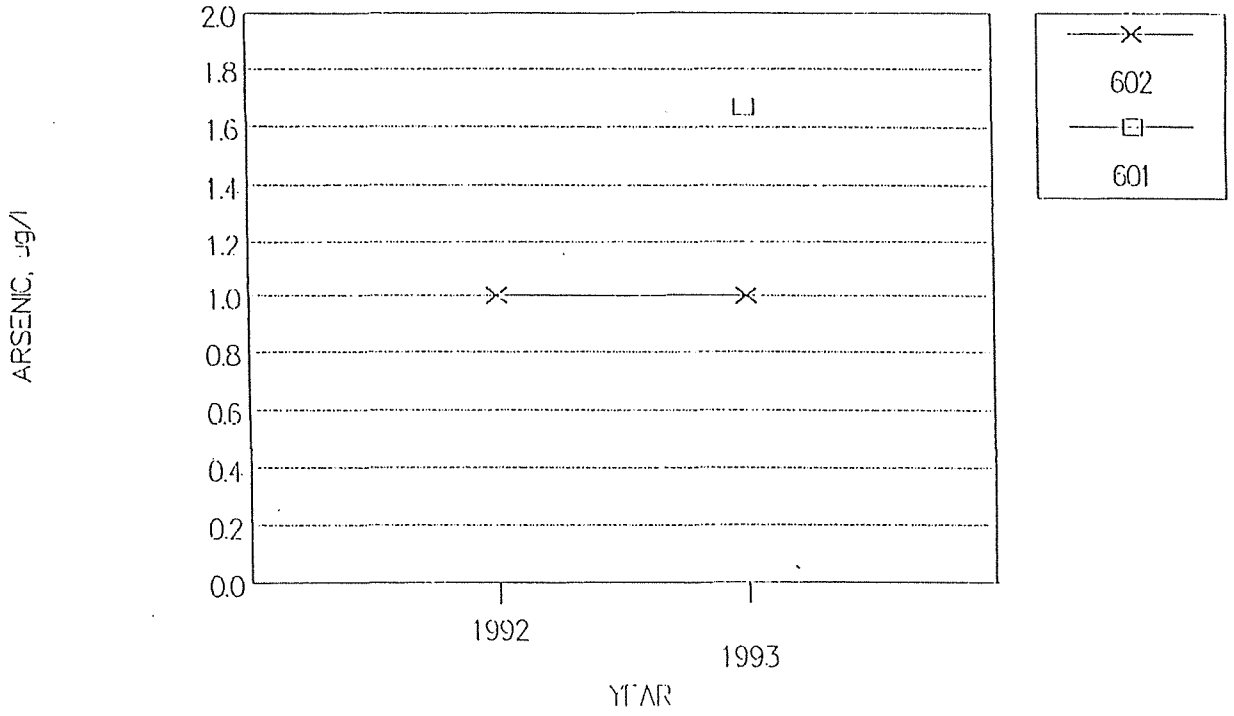

FIGURE 47. WATER QUALITY TREND CHART

SUBDIVISION F SURFACE WATERS

In general, parameter concentrations are stable for all monitoring wells other than MW-544 and MW-551. Increasing concentrations of chloride, selenium and sulfate at well MW-544, and chloride, strontium and sulfate at well MW-551, are considered to be due to the "punky" coal area, as outlined above. Although increasing, the concentrations of chloride at well MW-544 are well below the water quality guidelines. Selenium exceeded the water quality guideline of 0.010 mg/l at well MW-544 during 1993. The concentrations of chloride at well MW-551 are also well below the water quality guideline.

Statistical Analysis

Use of Historical Monitoring Data

The discussion above, along with examination of the water quality data plots for this subdivision, provide a basis for evaluating the water quality conditions at the monitoring locations. Additional data plots in Appendix E include various exploratory statistical methods to assist in determining the applicability of statistical analyses to the data.

The available data begin in late 1988 and were obtained almost quarterly, with some recent gaps. All data appear usable. The monitoring histories are not long enough to exhibit distinct changes in the long term.

Selection of a Statistical Test

Some monitoring histories exhibit sharp, consistent increasing trends (see trend charts), while others appear stable. Among the trending histories are several obtained at wells considered upgradient (e.g., chloride, selenium and sulfate at well MW-544 in Section 31, and chloride, strontium and sulfate at well MW-551 in Section 32). Because of this, comparisons in concentrations between upgradient wells and downgradient wells should not yet be attempted. Intra-well comparisons--control charts and regression--are appropriate.

Methods and Calculations

Sections 1 and 2 of Appendix D discuss regression and control chart methods, respectively.

Error Rates

Sections 1 and 2 of Appendix D discuss the error rates associated with regression and control chart methods. The probability of incorrectly identifying a trend using regression, for a history that merely exhibits trend induced by random variability, is 1%.

Discussion

The results of the trend and control chart tests included in Appendix E characterize each well according to whether it exhibits one or more significantly increasing trends among its reportable parameters. Table 13 summarizes the results of examining the regressions and control charts provided in Appendix E. Reference to the presence of trends is indicated as "yes" or "no", with "yes" indicated for trends which are readily apparent and of sufficient magnitude.

Upgradient wells MW-544 (Section 31) and MW-551 (Section 32) exhibit strong changes. In well MW-544, chloride concentrations doubled between 1991 and 1993; selenium concentrations tripled between 1989 and 1993; and sulfate concentrations increased 20% between 1989 and 1993. All were statistically significant trends. Of these three trending parameters, selenium and sulfate have exceeded their respective water quality guidelines of 0.010 mg/l and 250 mg/l, respectively. Although not exhibiting trending behavior, boron and strontium also exceed their respective water quality guidelines of 0.75 mg/l and 0.05 mg/l.

TABLE 13

RESULTS OF TREND ANALYSIS FOR REPORTABLE PARAMETERS
SUBDIVISION F

Well	Well Location	Trends Present (Direction)	Parameter
Section 5			
531	Upgradient	No	
533	Upgradient	No	
534	Upgradient	No	
535 - 542	Downgradient	No	
Section 31			
543	Upgradient	No	
544	Upgradient	Yes (Increase)	chloride, selenium, sulfate
546	Upgradient	Yes (Decrease)	sulfate
547	Downgradient	Yes (Decrease)	chloride, strontium
548	Downgradient	No	
549	Downgradient	Yes (Decrease)	sulfate
Section 32			
550	Upgradient	No	
551	Upgradient	Yes (Increase)	chloride, strontium, sulfate
552	Upgradient	No	
553	Upgradient	No	
554	Downgradient	No	
555	Downgradient	Insufficient Data	

In upgradient well MW-551 (Section 32), chloride concentrations quintupled between 1989 and 1993; strontium concentrations doubled between 1990 and 1993; and sulfate concentrations increased almost an order of magnitude between 1990 and 1993. Of these trending parameters, strontium and sulfate have exceeded their respective water quality guidelines.

Because of this evidence of change, suppose that wells 544 and 551 are dropped from the list of upgradient wells. Assume that the remaining upgradient wells truly represent upgradient conditions. From the average concentrations of each parameter at these seven remaining wells tolerance limits can be developed for screening the averages at other wells in the subdivision, following the same approach as utilized in the Subdivision DI analysis. Table 14 presents the tolerance limits for the four reportable parameters consistently detected in wells within Subdivision F.

TABLE 14

TOLERANCE LIMITS - SUBDIVISION F

Parameter	Mean (mg/l)	Standard Deviation (mg/l)	Sample Size	ANOVA P-Value	Tolerance Limit (mg/l)
Boron	0.552	0.665	7	< 1.0E-6 %	2.81
Chloride	5.19	7.16	7	< 1.0E-6 %	29.5
Strontium	1.67	3.60	7	< 1.0E-6 %	13.9
Sulfate	342	622	7	< 1.0E-6 %	2,456

Notes: Mean is the mean value of the average background concentrations. Standard Deviation is the standard deviation of the average background concentrations. Sample size is the number of upgradient wells used. ANOVA P-Value is the Analysis of Variance P-Value used to estimate the average concentrations and standard deviation of the averages; the very low values confirm the significance of the assumption of spatial variability. Tolerance Limit is the one-sided upper 95%-coverage, 95%-confidence tolerance limit.

Table 15 provides a summary of monitoring locations and parameters for which recent average concentrations exceed their tolerance limits as calculated above.

TABLE 15

TOLERANCE LIMITS EXCEEDANCES - SUBDIVISION F

Well	Well Location	Parameter	Approximate Average Concentration (mg/l)	Tolerance Limit (mg/l)
Section 5 None				
Section 31				
544	Upgradient	Boron	6	2.81
544	Upgradient	Chloride	75	29.5
544	Upgradient	Sulfate	2,800	2,456
547	Downgradient	Chloride	30	29.5
Section 32				
551	Up	Chloride	45	29.5

Additionally, chloride concentrations in well MW-541 are close to the tolerance limit. Individual concentrations sometimes exceed the calculated tolerance limit. However, the tolerance limit approach as utilized for this subdivision, applies to the average parameter concentrations at the monitoring location only.

The table above indicates that wells MW-544, MW-547, and MW-551 exhibit statistically significant evidence of adverse impacts to ground water. However, as indicated previously, the "impacts" are generally suspected of being related to ground water contact with weathered coal, and not due to the ash disposal.

ARSENIC

Arsenic has been consistently (50% or more of the time) detected at very few monitoring locations. Table 16 summarizes the monitoring well locations at which arsenic has been consistently detected.

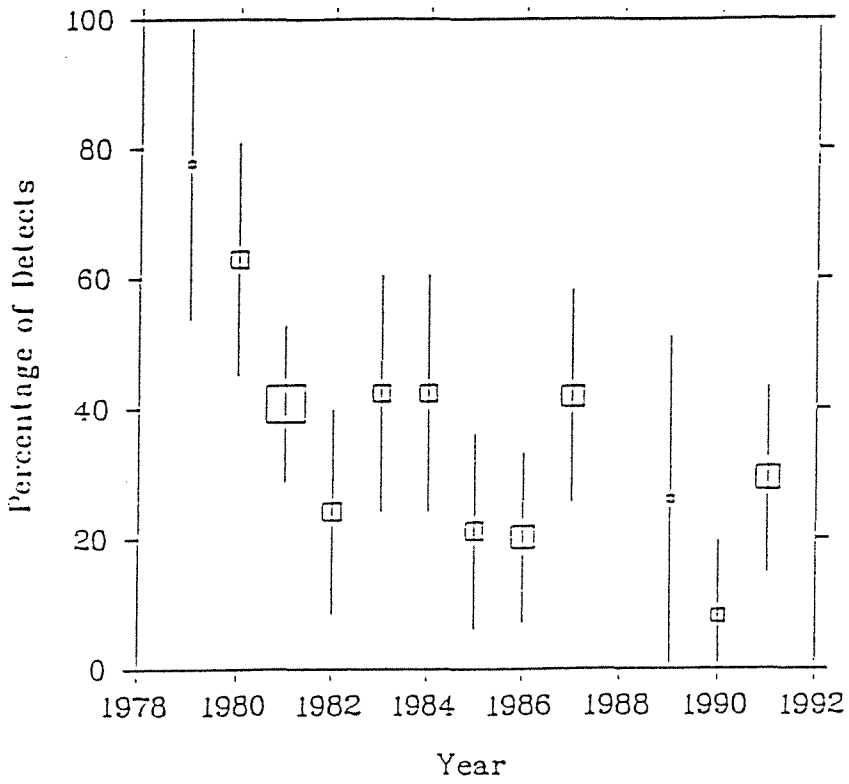

TABLE 16

CONSISTENT DETECTIONS OF ARSENIC - CCS MONITORING WELLS

Well	Well Location	Detection Period	Approximate Range of Concentrations (mg/l)
Subdivision DII			
MW-14	Downgradient	1979 - 1987	0.001 - 0.010
MW-13	Downgradient (Additional)	1979 - 1987	0.001 - 0.006
Subdivision E			
MW-8	Additional	1979 - 1987	0.001 - 0.009
Subdivision F			
MW-544	Upgradient	1989 - 1992	0.020 - 0.050

Recent observations have typically been non-detects, and can be taken as evidence that conditions have changed, but the number of observations are insufficient to quantify the extent or consistency of the change.

Overall, evidence is that arsenic concentrations in ground water have improved (decreased). This can be demonstrated by examining the detection frequency over time. The following plot, in "high-low-close" format, shows how the detection frequency in subdivisions A through DII has varied through 1991.

A summary of arsenic detection is shown for each year. A square is positioned at the observed detection frequency, P. The dimensions of the square are directly proportional to the number of arsenic measurements, N. The line extending above and below the square is an approximate confidence interval. Its half-length is three times the Normal-theory approximate estimator of the standard error, (P*(1-P)/N). Because N*P and N*(1-P) are typically in the 10 to 90 range, this approximation is good, and the confidence levels are about 99.5+%. Therefore, non-overlapping ranges are strong evidence of significant differences in detection frequency.

Initially (1979-81) there is a strong and significant trend toward lower detection frequencies. During the last ten-year period a moderate trend toward a lower percentage of detects is evident. Although biases due to undersampling of wells could have been introduced, the preponderance of non-detects in 1992 and 93 (not shown)--almost 0% detection--continues the trend.

Because recent arsenic observations are almost entirely non-detects, an adequate monitoring method is to carefully examine any new quantified value above historical detection limits.

SUMMARY AND RECOMMENDATIONS

STATISTICAL ANALYSES

- Linear regression to test for long-term trends and control charting to monitor and evaluate stable histories are the statistical methods of choice for most of the subdivisions.

- In Subdivisions D and F, where several upgradient wells are available for comparison, tolerance limits developed from upgradient historical averages serve as an adequate screening approach for ground water impact at other wells. Tables 7 and 14 summarize these tolerance limits.

- Some historical data should not be included when developing regression lines, control charts, or tolerance limits, because ground water conditions have changed during distinct, observable periods possibly tied to facility activities. This is particularly true for Subdivisions A and B. The specific time periods have been noted.

- Future arsenic and selenium results should be considered significant when quantifiable above historical detection limits. At certain wells with historically quantifiable concentrations of these parameters, such as MW-544, the intra-well techniques recommended for the other reportable parameters (regression and control charting) should be applied.

- In general, these data are not complicated by violation of statistical assumptions, such as non-normal distribution, changes of variability, seasonality, large proportion of non-detects (except for arsenic and selenium) and correlation over time. Where these assumptions are violated, such as the seasonality observed in well MW-8, their violation is unimportant or can be handled with a simple and appropriate technique, such as transforming the data by taking logarithms of the values. These cases have been noted in the text.

OPERATIONS AND MONITORING

- Water quality trends suggest that the extensive pond repair program has made a favorable impact on ground water and surface water.

- Continued monitoring is necessary to fully evaluate long-term water quality trends.

- Based on the findings of this evaluation, the monitoring locations can be modified as shown on Table 17. Sixteen locations are recommended to be deleted from the monitoring program. Another fourteen locations should be re-evaluated for possible deletion after an additional monitoring period of two years.

- Based on the findings of this evaluation, boron, chloride and sulfate are the most indicative parameters for tracking water quality trends and should continue to be used in the monitoring program. Arsenic, selenium and strontium are less indicative and should be dropped from the list of required reporting parameters.

TABLE 17

WATER QUALITY MONITORING LOCATION RECOMMENDATIONS

Subdivision	Continue to Monitor	Monitor for 2 Years and then Re-Evaluate	Delete from Program **
A	MW-23, 24, 83 SW-109, 114	MW-17, 18, 22, 90, 91	MW-16, 20, 21, 87

APPENDIX A

1993 SOLID WASTE MANAGEMENT FACILITY ANNUAL REPORT

SOLID WASTE MANAGEMENT FACILITY ANNUAL REPORT

FOR

COOPERATIVE POWER ASSOCIATION

COAL CREEK STATION
PO BOX 780
UNDERWOOD, ND 58576

JANUARY 1, 1993 TO DECEMBER 31, 1993

SPECIAL WASTE DISPOSAL SITES ACTIVITY AND STATUS

PERMIT SU-033 Section 16 Disposal Area

The section 16 disposal area includes the Section 16 disposal site, Ash Pond Cells #91 and 92, the Recycle Pond, and the Plant Drains Pond (Figure 1).

Section 16 Disposal Site
In 1993, a total of approximately 21 tons of C & D material were placed in this site. Approximately 170 tons of asbestos material from the demolition of Cooling Tower #93 were placed in the SW 1/4 of the construction waste landfill portion of the disposal area.

Ash Pond Cell #91
This pond cell was out of service for most of the year for installation of the HDP liner. Approximately 77,330 tons of fly ash were hauled to this pond for use in the liner construction.

Ash Pond Cell #92
This pond cell was in service the entire year. Approximately 288,413 tons of bottom ash and 87,947 tons of scrubber slurry were piped to this site in 1993.

Recycle Pond
The Recycle Pond was in service through all of 1993. It will be taken out of service in 1994 when the new Plant Drains Pond is fully operational.

Plant Drains Pond
The Plant Drains Pond was constructed in 1993 to replace the Recycle Pond. This pond went into service in October 1993. Both the Plant Drains Pond and the Recycle Pond remained in service the rest of the year due to operational needs to get the water to the evaporation ponds.

PERMIT SU-091 Section 5 Disposal Area

This disposal site was filled to capacity in 1988. The site was temporarily capped with two feet of clay and seeded in 1990. Future expansion of the site is planned to the north and south. Final reclamation will not be done until the entire disposal site has been used.

PERMIT SU-095 Sections 31 and 32 Disposal Sites

Section 31 Disposal Site
This site was filled to capacity in 1992 and taken out of service in 1993. In the summer of 1993, final reclamation was completed in accordance with NDAC 33-20-04.1.

Section 32 Disposal Site
This disposal site was placed in service in 1993 and was active throughout the year. Approximately 389,180 tons of fly ash were disposed at this site in 1993. Approximately 54 tons of asbestos material from the demolition of Cooling Tower #93 was placed in the NW 1/4 of the disposal area.

PERMIT SU-118 Evaporation Ponds #91-94

Evaporation Pond #91
This pond was relined in the summer of 1990 and became operational in November 1990. It was in continuous service in 1993.

Evaporation Pond #92
This pond was relined during the summer of 1991 and became operational in December 1991. It was in continuous service in 1993.

Evaporation Pond #93
This pond was relined during the summer of 1992 and became operational in November 1992. It was in continuous service in 1993.

Evaporation Pond #94
This pond was relined late in 1991 and put into service in February of 1992. It was in continuous service in 1993.

APPENDIX C

1993 WATER QUALITY MONITORING PROGRAM

COAL CREEK STATION
WATER QUALITY MONITORING PROGRAM
SPRING 1993

Coal Creek Station's groundwater and surface water sampling program to be performed between March 15 - April 14, 1993.

Wells to be monitored for field parameters:

* Subdivision DI Wells: 9-10, 48-57, 59, 66-68, 71, 74-75, 208-209
* Subdivision DII Wells: 12-15, 42-46, 69, 72-73
* Subdivision C Wells: 40-41, 58, 60-65, 76
* Subdivision E Wells: 7-8, 11, 70

Surface waters to be monitored for field parameters:

* Subdivision DI Surface Waters: 108, 126-127
* Subdivision C Surface Waters: 104, 107
* Subdivision E Surface Waters: 101-103, 115, 117, 123

FIELD DATA TO BE COLLECTED:

* Sample Period
* Date Prepumped
* Volume Prepumped
* Date Sampled
* Weather Conditions
* Water Level Depth Below Top of Well Casing

COAL CREEK STATION
WATER QUALITY MONITORING PROGRAM
SUMMER 1993

Coal Creek Station's groundwater and surface water sampling program to be performed between May 15 - September 14, 1993.

Subdivision F; May 15 to June 14.

Wells to be Monitored for Field and Lab Parameters:
* Subdivision F: 543-544, 546-547, 548-549, 550-555, 531-542
Surface Waters to be Monitored for Field and Lab Parameters:
* Subdivision F: 601-602

Subdivision A & B; June 15 to July 14.

Wells to be Monitored for Field and Lab Parameters:
* Subdivision A: 16-18, 20-24, 83, 87, 90-91
* Subdivision B: 29-32, 38, 79-82

Wells to be Monitored for Field Parameters Only:
* Subdivision A: 26-28, 39, 47, 84-86, 88-89
* Subdivision B: 1-5, 33-37, 77-78, 322-323

Surface Waters to be Monitored for Field and Lab Parameters:
* Subdivision A: 109, 114
* Subdivision B: 105, 113, 118

Subdivision E; July 15 to August 14.

Wells to be Monitored for Field and Lab Parameters:
* Subdivision E: 7-8

Well to be Monitored for Field Parameters Only:
* Subdivision E: 11, 70

Surface Water to Monitored for Field and Lab Parameters:
* Subdivision E: 101-103, 115, 117, 123

Subdivision DI, DII, and C; August 15 to September 14.

Wells to be Monitored for Field and Lab Parameters:
* Subdivision DI: 9-10, 49-55, 57, 71, 74
* Subdivision DII: 12-15, 42-43, 72-73
* Subdivision C: 60-65

Wells to be Monitored for Field Parameters Only:
* Subdivision DI: 48, 56, 59, 66-68, 75, 208-209
* Subdivision DII: 44-46, 69
* Subdivision C: 40-41, 58, 76

Surface Waters to be Monitored for Field and Lab Parameters:
* Subdivision DI: 108, 126-127
* Subdivision C: 104, 107

COAL CREEK STATION
WATER QUALITY MONITORING PROGRAM
SUMMER 1993 (Continued)

FIELD DATA TO BE COLLECTED DURING EACH COLLECTION PERIOD:

* Sample Period
* Date Prepumped
* Volume Prepumped
* Date Sampled
* Weather Conditions
* Water Level Depth Below Top of Well Casing
* Temperature, pH, specific Conductance
* Sample Collection Technique (Bailer or Bladder Pump)
* Additional Comments

Copies of the field data sheets are to be submitted to the Environmental Specialist within 14 days after the end of each sample period.

LABORATORY PARAMETERS TO BE ANALYZED:

* Reportable Parameters: SO4, Cl, As, B, Se, Sr

* Internal Parameters: Na, K, Mg, Ca, ALK (Total, Bicarbonate & Carbonate), pH-lab, Specific Conductance

* Special Internal Analysis:

Monitoring Wells: 543-544, 548-549, 552-555, 533-534, 537-538, 14-15, 74

Parameters: Ag, Ba, Be, Cu, Cd, Cr, F, Hg, Ni, NO3-N, Pb, Zn

YEARLY QA SPLIT TO CONTRACT LABORATORY:

To be Collected With Subdivision E Samples

Monitoring Wells: 7, 8, 11, 70
Surface Water: 101

* Specific Conductance, pH, SO4, Cl, As, B, Se, Sr

COAL CREEK STATION
WATER QUALITY MONITORING PROGRAM
FALL 1993

Coal Creek Station's groundwater and surface water sampling program to be performed between October 15 - November 14, 1993.

Wells to be monitored for field parameters:

* Subdivision F: 543-544, 546-549, 550-555, 531-542
* Subdivision A: 16-18, 20-24, 26-28, 39, 47, 83-91
* Subdivision B: 1-5, 29-38, 77-82, 322-323
* Subdivision E: 7-8, 11, 70

Surface waters to be monitored for field parameters:

* Subdivision F: 601-602
* Subdivision A: 109, 114
* Subdivision B: 105, 113, 118
* Subdivision E: 101-103, 115, 117, 123

FIELD DATA TO BE COLLECTED:

* Sample Period
* Date Prepumped
* Volume Prepumped
* Date Sampled
* Weather Conditions
* Water Level Depth Below Top of Well Casing
* Temperature, pH, Specific Conductance
* Sample Collection Technique (Bailer or Bladder Pump)
* Additional Comments

Copies of the field data sheets are to be submitted to the Environmental Specialist by December 1, 1993.

APPENDIX D

STATISTICAL ANALYSIS METHODS UTILIZED

STATISTICAL ANALYSIS METHODS UTILIZED

1.0 ORDINARY LEAST SQUARES (REGRESSION)

Description of Technique

Over time, data obtained by analyzing samples at each monitoring well constitute a series (T_i, X_i) in time, where:

T_i is the time the i^{th} sample was obtained, i = 1, 2, ..., N
X_i is the value of the analyte at time T_i
The T_i are ordered by increasing time: $T_1 < T_2 < ... < T_N$

Ordinary Least Squares (OLS) assumes that some preset mathematical transform, $Y_i(X_i)$, is a linear function of time plus an independent random component:

$$Y_i = aT_i + b + e$$

The (unknown) numbers a and b are parameters of the model. The random variable e models deviations of the dependent values Y_i from linearity. Values of e for different times and different wells are supposed independent, identically distributed, of mean 0, and finite (but unknown) constant variance. The validity of these assumptions--independence, identical distribution, zero mean, and constant variance--can be assessed during the process of estimating the model parameters.

The EPA guidance and its 1992 update, *Statistical Analysis of Ground-Water Monitoring Data at RCRA Facilities, Addendum to Interim Final Guidance,* recommend and discuss only a logarithmic transformation of the data (although others are allowable under the regulations). Hence, in the following description, the alternatives considered are either $Y_i = X_i$ or $Y_i = \log(X_i)$, where log() is the natural logarithm. The description also provides a basis for determining whether to apply the logarithm transformation or not.

The OLS estimators of a and b are (Draper and Smith, *Applied Regression Analysis,* Second edition, section 1.2)):

$\hat{a}$	$= S_{TY}/S_{TT}$	[Estimated slope]
$\hat{b}$	$= \bar{Y} - \hat{a}\bar{T}$	[Estimated intercept]
$\bar{Y}$	$= S_Y/N$	[Mean dependent value]
$\bar{T}$	$= S_T/N$	[Mean independent value]
S_{TY} = Sum of all $(T_i - \bar{T}) * (Y_i - \bar{Y})$		[Sum of products]
S_{YY} = Sum of all $(Y_i - \bar{Y}) * (Y_i - \bar{Y})$		[Sum of squares]
S_Y = Sum of all Y_i		
S_T = Sum of all T_i		

The values of the Y_i predicted by the model are therefore:

$$\hat{Y}_i = \hat{a} T_i + \hat{b}$$

and the *residuals* are the differences between the actual values and the predicted values:

$$R_i = Y_i - \hat{Y}_i$$

The variance of e is estimated by s^2:

$$s^2 = S_{RR}/(N-2)$$

$$S_{RR} = \text{Sum of all } (R_i - \bar{R}) * (R_i - \bar{R}) = R_i * R_i$$

Application

1. The data should be graphed as a time series plot with the horizontal axis showing time and the vertical showing concentration (or its logarithm). If the historical tendency is not approximately linear or log-linear, only the most recent data should be retained for this test. As many data as possible, proceeding back in time from the present, should be retained while maintaining an almost-linear or log-linear pattern.

2. If evidence of seasonality or other periodic behavior is evident, this should first be removed or incorporated into the OLS model (by including a categorical season as a second independent variable). The reportable parameters have not exhibited important seasonal fluctuations. Therefore, the details of these procedures are not described here because of their increased complication and relative unimportance. If seasonality is removed from the data, the seasonal effects should be reported.

3. The value of X to use for any non-detects should at first be half the detection limit. If the results of the subsequent trend analysis would depend on the numerical treatment of non-detects, then a non-parametric assessment of trend should be applied in place of the remaining steps. Sen's estimator as described in Gilbert, *Statistical Methods for Environmental Pollution Monitoring*, should be used.

4. At each well (both upgradient and downgradient), both OLS models ($Y_i = X_i$ and $Y_i = \log(X_i)$) should be fit to the data. The one whose residuals appear distributed most like a Normal distribution, as tested using techniques discussed in Section 1.1 of the Addendum to the EPA guidance, should be the one selected.

5. A two-sided confidence interval around the slope, b, should be constructed assuming the distribution of the e is approximately Normal. The endpoints of this interval are given by

$$\hat{a} \pm t(n-2, 1-0.005)s/\sqrt{S_{TT}}$$

where t(n-2, 1-0.005)is the 100(1-0.005) percentage point of the Student t-distribution with (n-2) degrees of freedom. (Typically percentage points are given in the table below.) Assuming the model is correct, this procedure will cover the true value 99% of the time that it is applied.

6. For each well where the value 0 lies within the confidence interval for the slope constructed in step 5, the concentrations will be considered (recently) stable. For the other wells, the concentrations will be considered significantly increasing (decreasing), depending on whether the estimated slope $\hat{a}$ is positive (negative). This result--stable, increasing, or decreasing--should be reported for each well.

7. The validity of the model should be assessed using techniques described in the EPA guidance, its Addendum, and in standard texts (such as Draper and Smith). These techniques will include statistical and/or graphical tests for independence, identical distribution, and constant variance of the residuals. However, lack of validity should be used to qualify the result reported in step 6, but not to change it.

2.0 CONTROL CHARTS

Description of Technique

Control charts graphically portray the average value of analyte concentrations attained in past sampling. They also establish limits above and below this average value, limits based on the variability of previous results. The limits are placed sufficiently far from the average so as to reduce the probability that a chance deviation in a subsequent analytical result would fall beyond the limits. Therefore, obtaining a result beyond the limits will be evidence of a change. Yet, the limits are placed close enough to the average for the control chart technique to correctly and quickly identify changes when they occur.

The probability model for control charting is similar to that for ordinary least squares. The terminology established in the description of OLS will be used here. The model is:

$$Y_i = b + e$$

with the same assumptions on e. The absence of the aT_i term means that analyte concentrations are supposed stable over time. Therefore, control charting supplements the OLS analysis: control charts can be developed only for those monitoring histories deemed not to be significantly trending.

The control chart technique to be used is that developed and recommended by the EPA monograph, *Evaluation of Control Chart Methodologies for RCRA Waste Sites.* Although not an expression of official EPA views, this monograph is a primary reference for the EPA guidance. This technique is the classical Shewhart-CUSUM method, but it varies from traditional applications by setting control limits at distances more appropriate for ground water monitoring data.

The Shewhart method is the technique described in the introductory paragraph to this section. It's specification requires two data to be decided before the technique can be applied:

1. The distance of the control limits from the mean is a multiple, U, of the standard deviation. The value of U must be provided.

2. A procedure for deciding which historical data to use for estimating the mean and standard deviation must be provided.

In particular, at the onset of monitoring no historical data are available. Therefore results must be gathered until enough are available to estimate the mean and standard deviation. During this period a control chart cannot be produced. The number of sampling rounds required is called the *learning period.*

The one-sided CUSUM (for CUmulative SUMmation) method computes a sum, S, for each result:

$$S_i = \max \{0, Y_i - k + S_{i-1}\},$$

where k is a parameter of the CUSUM method. When S_i exceeds a preset value h, the series is considered out of control and a statistically significant increase is noted. The value of S_i is then reset to 0. The values of k and h must be provided for a complete description of this scheme.

To make this into a two-sided procedure, the one-sided procedure is simultaneously applied to the negatives of the Y_i. Thus,

$$S_i' = \max \{0, -Y_i - k + S_{i-1}'\}$$

is also computed and compared to the CUSUM threshold h.

Specifying the CUSUM chart in addition to the Shewhart chart, therefore, requires two additional data to be specified.

3. The value of k must be provided.

4. The value of h must be provided.

The method described in the EPA monograph is:

> "...U=4.5, h=5, and k=1 for the first 12 sampling periods [rounds] after the eight period learning stage, and then U is reduced to 4.0, k is reduced to 0.75, and these two parameters are held at these values for all subsequent periods. Adjustments in sample means and sample standard deviations are made after sampling periods 4, 8, 12, 20, and 32, following the learning stage."

Application

1. Control charting should be attempted for all histories not showing a significant linear or loglinear trend as established by OLS regression.

2. Valid results from control charts require that data be approximately Normally distributed. Therefore, data should be tested for Normality using techniques discussed in the Addendum to the EPA guidance. If neither the data nor their logarithms appear normally distributed, testing at a 99% level, then control charts should not be applied.

3. Non-detects should at first be replaced by one-half the detection limits. Control charts should not be developed if more than 25% of the data are non-detects.

4. The combined Shewhart-CUSUM scheme described in the EPA monograph should be applied. It should be shown graphically as a time-series plot of the data upon which the running means and control limits are superimposed. The CUSUM chart should be separately plotted on a parallel time axis. Any out of control points should be highlighted.

3.0 TOLERANCE LIMITS

Description of Technique

As in the discussion of OLS estimators (Section 1.0), the data for a given reportable parameter at a given well, after a possible transformation, will be designated Y_i, i = 1, 2,..., N. A one-sided upper tolerance limit is computed assuming that the distribution of the Y_i is Normal (which is why a transformation of the original data must be considered). The limit is the sum of the mean and a multiple, K, of the standard deviation of the data.

The following definitions are utilized:

$TL = \bar{Y} + K * s$ [Upper tolerance limit]

$\bar{Y} = S_Y/N$ [Mean dependent value]

$s^2 = S_{YY}/(N-1)$

S_{YY} = Sum of all $(Y_i - \bar{Y}) * (Y_i - \bar{Y})$ [Sum of squares]

S_Y = Sum of all Y_i

The value K depends on the coverage and confidence of the tolerance limit, as well as on the number of data, N. Hahn and Meeker in *Statistical Intervals* (Wiley, 1991) provide tables of K for typical coverages and confidence levels. The USEPA, in its regulations and guidance documents for RCRA ground water monitoring, recommends (but does not require) coverage and confidence of 95%. For RCRA monitoring applications, the confidence is not allowed to exceed 95%. The following stable is a portion of Hahn & Meeker's Table A.12c, *Factors... for Calculating Normal Distribution One-Sided 100(1-α)% Tolerance Bounds:*

	p=0.950 (coverage)
N	1-α = 0.950 (confidence)
2	26.260
3	7.656
4	5.144
5	4.203
6	3.708
7	3.399
8	3.187
9	3.031
10	2.911
15	2.566
20	2.396
50	2.065
240	1.819
∞	1.645

Applications

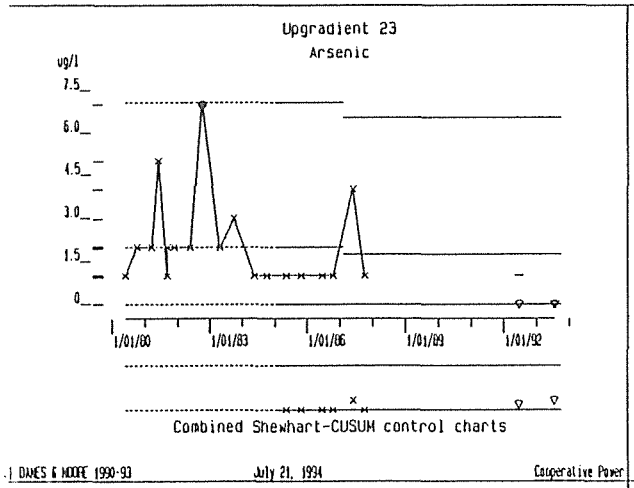
Using historical monitoring data to establish an upper limit for future results

In this application, a time period representing baseline (historical or unimpacted) conditions is selected for a single well. The analyses collected for one parameter comprise the data for developing the tolerance limit. These data should:

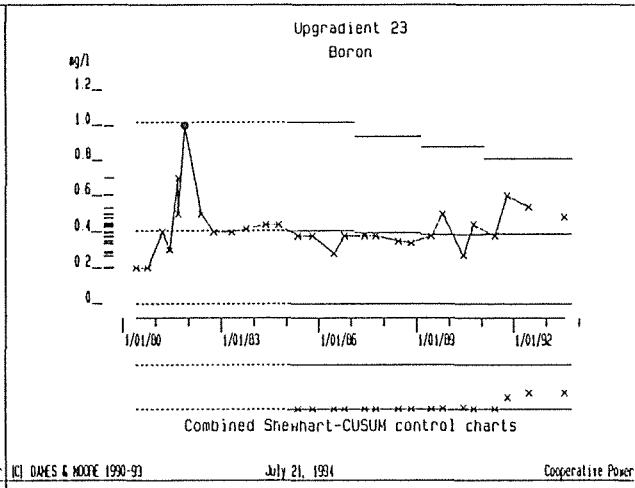
- Be uncorrelated over time
- Exhibit stability (no significant long-term trend and no significant changes in variability with time)
- Exhibit no seasonal fluctuations (if they do, the seasonal component can first be estimated and removed)
- Be approximately normally distributed

The tolerance limit, TL, computed using the formula in Section 3 of this appendix, is a limit against which all future values from this well can be compared. Any future result exceeding this limit has a 95% chance (the confidence) of lying above the lowest 95% (the coverage) of all values projected from the baseline period. This is a strong indication that the result is unusually high. Two such results in succession, or a longer period with a high proportion of such results, both indicate that a statistically significant change has occurred in ground water conditions near this well.

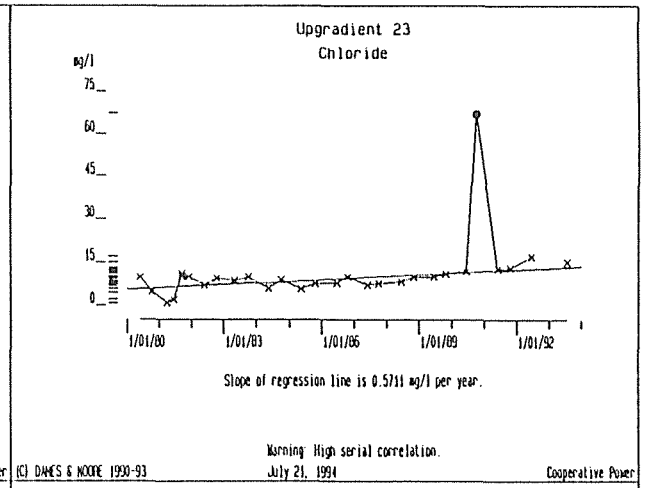
Using background average concentrations to establish an upper limit on average concentrations at any other well



In this application, a collection of upgradient or background wells is selected as representative of the hydrogeologic unit being monitored by additional wells. For a given parameter, the data in this application become average concentration at each well. The number of data, N, equals the number of wells. Therefore, at least two, and preferably more (given the large value of K for N=2 in the table in Section 3 of this appendix) upgradient wells are needed for this procedure.



This application of tolerance limits is an approximation, because the variability of any average depends on the number of observations contributing to that average. An improved way to estimate the average concentrations and the standard deviation of the averages is with Analysis of Variance (which still produces only approximate results). However, with long, consistent monitoring histories in the background and the comparison wells, the difference in procedures is of little consequence, and the approximation is a good one.



The tolerance limit computed from the average concentrations at upgradient wells serves to screen average concentrations (not individual concentrations) at any other wells. An average concentration above the tolerance limit is statistically significant evidence that ground water near a monitoring well is different than the ground water monitored by the background wells, and that the difference is not due to natural spatial fluctuations in ground water quality alone.

[B:\COOPPWR.RPT]

1.0 INTRODUCTION

This report provides an evaluation of the Water Quality Monitoring Program at Coal Creek Station and at selected locations at the adjacent Falkirk Mine. These facilities are located in McLean County near Underwood, North Dakota (Figure 1). This document is based on our work plan dated June 27, 1991 and is performed in accordance with our Master Service Agreement with Cooperative Power Association (#548113) dated March 15, 1991.

The primary purpose of this study is to review and revise the current water quality monitoring plan to be more cost effective and reflective of current needs. This intent is based on a database consisting of thirteen years of water quality data and completion of thirty-one site-specific hydrogeology and related reports. The product of this evaluation is a revised Water Quality Monitoring Plan (WQMP), given in Section 6.0 of this report.

2.0 BACKGROUND

Coal Creek Station (CCS) is a two unit 1100 MW coal fired power plant. Coal is supplied exclusively by the Falkirk mine which is immediately north of Coal Creek Station. A generalized map of the site is presented as Figure 2.

Initial subsurface exploration at the proposed CCS site began in 1974. Unit No. 1 began operation in 1979 and Unit No. 2 came was completed in 1980. Water which is used during plant operations is dissipated from a series of evaporation ponds. Solids (primarily ash, with some lime sludge) are deposited in ash ponds at Coal Creek Station and at three engineered solid waste disposal areas at the Falkirk mine. The ground water monitoring program is in place to monitor impacts to ground water and surface water that may be associated with power plant activities. The data that have been collected are in compliance with North Dakota State Department of Health (NDSDH) requirements and are submitted annually to NDSDH.

Ground water and surface water data have been collected from around and within natural and engineered ponds since 1979. Engineered ponds at Coal Creek Station include Evaporation Pond 91 (formerly Lower North Evaporation Pond, LNEP) , Evaporation Pond 92 (former Upper North Evaporation Pond, UNEP), Evaporation Pond 93 (former Lower East Evaporation Pond, LEEP), Evaporation Pond 94 (former Upper East Evaporation Pond, UEEP), Ash Pond 91 (former West Half South Ash Pond, W/SAP), Ash Pond 92 (former East Half South Ash Pond, E/SAP), Section 16 Disposal Area (former East Ash Pond, EAP), River Water Holding Basin, Extended Basin, and Recycle Basin. The engineered areas at Falkirk mine include Section 5 Disposal Area, Section 31 Disposal Area, and Section 32 Disposal Area.

3.0 KNOWN HYDROGEOLOGICAL CONDITIONS

More than 30 reports have been completed to evaluate hydrogeological conditions. The documents are separated between Coal Creek Station and Falkirk mine because of different geology, different use, and different investigative histories. The reports are listed in Appendices A and B (Coal Creek Station and Falkirk Mine, respectively) with brief summaries of the activities and/or findings from each of the investigations.

The results of the investigations have provided a comprehensive hydrogeological understanding of the area. A summary of known hydrogeological conditions is given in the following sections.

3.1 Coal Creek Station

Ground water data have been collected from more than 100 ground water monitoring wells. The surface water data have been collected from approximately 20 natural ponds, sloughs, and waterways and approximately 20 engineered ponds, disposal areas, and related discharges. More than five hundred soil borings have been drilled at Coal Creek Station. These borings, which range from 4 to 400 feet deep, have been used for engineering and hydrogeological purposes. A summary of known hydrogeological conditions at Coal Creek Station is listed below.

3.1.1 Geology

The geology of Coal Creek Station has been established from findings of the completed reports. A generalized geological cross-section is provided as Figure 3. The unconsolidated surficial deposits are of the Coleharbor formation consisting of stratified and unstratified glacial drift. It appears that the drift is the result of three glacial advances. The near-surface materials are silty clay and sandy clay till with interbedded sand lenses. Bedrock is located along the north and south side of Coal Creek Station as the flanks of the west-to-east drainage network of wetlands and legal drain system.

3.1.2 Ground Water Flow

Regional ground water flow in the vicinity of CCS is a subtle expression of the ground surface topography, which is influenced by the configuration of the eroded bedrock. The ground water flow is generally toward the wetlands in the central part of the site, except where locally affected by other factors, such as mounding beneath ponds. The ground water in the uplands is within the poorly consolidated bedrock, while the ground water in the lowlands is found in the glacial till.

3.1.3 Water Quality Impacts

Determination of the extent and magnitude of water quality impacts has been based on data from ground water and surface water monitoring locations. Recent electromagnetic survey information has also been useful. The findings indicate that there are several sources of water quality impacts (ponds). Contamination from the sources has been found to be widespread throughout the ground water flow system at the site.

3.2 Falkirk Mine

The hydrogeological setting of the Falkirk Mine area has been determined as part of the coal exploration and mining activities. The three ash disposal areas at the Falkirk Mine are located in areas that have been previously mined. There are 24 ground water monitoring wells at the Falkirk mine directly related to the ash disposal areas. Data from other nearby wells have also been used to evaluate hydrogeological conditions in additional areas of the Falkirk mine ash disposal areas. A summary of known hydrogeological conditions at Coal Creek Station is listed below.

3.2.1 Geology

The geology of the Falkirk Mine Disposal Area has been established from findings of the completed reports. A generalized geological cross-section is provided as Figure 4. Unconsolidated glacial till overlies the economically significant lignite beds of the Sentinel Butte formation. The Sentinel Butte formation is primarily composed of poorly consolidated carbonaceous shales, locally know as bedrock clays, and lignite beds. The Hagel A and Hagel B coal seams are considered to be local aquifers. A poorly cemented silty sandstone locally known as the Sheet Sand, also an aquifer, underlies the clay parting beneath the Hagel B Coal Bed. The Ash Disposal Areas are engineered facilities within the mined out area.

3.2.2 Ground Water Flow

Ground water flow in the Hagel B and the Sheet Sand is toward the south-southwest toward the Weller Slough Complex. The Hagel A aquifer has been breached and is dry and/or discharges to the next lower aquifer, depending upon the extent of mining activities. The geology, and therefore the ground water flow pattern, is disturbed in the vicinity of the disposal areas. The Hagel B aquifer is most likely to be impacted by releases from the ash disposal area since it is located at the base of the mined excavation and at the same elevation as the base of the ash disposal area. The Sheet Sand has been monitored because it is the next aquifer below the base of the disposal facility.

3.3.3 Water Quality Impacts

Ground water quality in this area is highly variable and difficult to monitor. The water quality is affected by exposure to weathered low quality coal associated with the erosional features and from mine tailings. Therefore it is difficult to establish comparative conditions with which to evaluate potential adverse water quality impacts associated with the disposal areas. Furthermore, ash impacts are expected to be minimal because of the clay lining of the engineered disposal areas.

4.0 WATER QUALITY DATABASE

The water quality and water level database which began in 1979, has 13 years of data, 206 sampling locations, data for 47 parameters, and contains 44,196 data points. The current WQMP includes 158 sampling locations and data for 35 parameters. A goal of this data evaluation is to reduce the number of sampling locations and number of parameters that are needed to adequately monitor representative ground water and surface water conditions at the site.

The following sections discuss (a) the monitoring programs that have generated these data and (b) a summarized description of the collected data.

4.1 Monitoring Program

The Coal Creek Station power plant was built as a "zero discharge facility". This concept means that water loss from the ponds was expected to be by evaporation, not by surface water discharge or ground water seepage. A network of ground water and surface water monitoring locations has been developed to monitor the effectiveness of this concept. The monitoring locations are listed in Appendix C. The existing Coal Creek Station ground water and surface water monitoring locations are shown on Figure 5 and 6, respectively.

A network of 15 wells were initially installed around the plant to monitor ground water conditions. Three surface water sample locations were initiated in 1980. Water samples from these locations were analyzed for 13 parameters. The monitoring locations expanded as additional investigations were conducted. A summary of the data locations and the date of first data collection event is given on Table 1.

In November 1985 a formalized Water Quality Monitoring Plan (WQMP) was developed for Coal Creek Station. The purpose of the WQMP was to establish monitoring locations and water quality parameters to evaluate potential impacts to the wetlands and shallow ground water in the area which may be associated with a facility. This plan proposed additional ground water and surface water monitoring

locations. The plan was implemented in 1986. It was recommended that three field parameters (field temperature, field pH, and field conductivity) and four laboratory parameters (sulfate, chloride, boron, and arsenic) be analyzed two times per year during the second and fourth quarters. It was also recommended that water level measurements be taken quarterly at all wells and surface water locations. The plan acknowledged that additional supplemental monitoring locations may be needed in the future depending upon the findings of the proposed monitoring program.

The Falkirk mine developed a concurrent monitoring program, however this program was designed to primarly support mining exploration and production. Wells installed by Falkirk and others were placed throughout the mine area.

Beginning in 1982 three ash disposal areas were designed and constructed for Coal Creek Station at the Falkirk mine (Section 5 Disposal Area, Section 31 Disposal Area, and Section 32 Disposal Area). A total of 24 ground water monitoring wells were installed in 1988. The monitoring wells are the basis of an established ground water monitoring plan developed in 1988 (Figure 7). Additional exploration monitoring wells in the immediate area of the disposal sites continue to be monitored by Falkirk.

The current WQMP has expanded to include Coal Creek Station and Falkirk mine monitoring locations. The current plan includes 123 monitoring wells, 26 surface water locations, 9 precipitation runoff monitoring locations, 35 parameters, and a monitoring schedule that varies from four times per year to every five years. The permitted Water Quality Monitoring Plan is presented in Appendix D.

Summaries of the WQMP are presented in tabular form for ease of review. The Sample Frequency for CCS Ground Water, CCS Surface Water, CCS Precipitation Runoff, and FM Ground Water are shown on Tables 2 - 5, respectively. The tables show the number of locations sampled during each quarter and during special events (every 5 years and/or runoff events). The tables are organized for each sampling group by physical tests, metal analysis, and inorganic tests respectively.

Table 6 shows a Comparison of Analytical Parameters that are tested from each of the sampling location groups. The list of analytical parameters differs for each sampling location group.

4.2 Data Summary

The water quality database contains numerous data points, some of which are not included in the WQMP. Data not included are primarily from limited sampling events and temporary or destroyed monitoring locations. Data that are included in the WQMP are summarized for representative locations in the tables below.

Representative sampling locations at Coal Creek Station are given in Table 7. The Coal Creek Station data are separated by Physical Tests, Inorganic Tests, and Metal Analysis in Tables 8 - 10, respectively. Minimum and maximum reported values are shown for each parameter.

Representative sampling locations at the Falkirk Mine are given in Table 11. The Falkirk Mine data are separated by Physical Tests, Inorganic Tests, and Metal Analysis in Tables 12 - 14, respectively. Minimum and maximum reported values are shown for each parameter.

Additional data not shown on these tables are the electromagnetic surveys that have been conducted annually since 1988. These data had been collected from a permanently established pattern around the Coal Creek Station ponds and the Falkirk Mine disposal areas. These data are referenced in Appendices A and B.

5.0 RECOMMENDED PLAN MODIFICATIONS

Water quality data have been collected for thirteen years from some of the monitoring locations. The discussion pertains to both Coal Creek Station and the Falkirk Mine Disposal Area. The general conclusions are the same, although the Falkirk data are less extensive. This section will discuss the (a) analytical parameters, (b) sampling locations, and (3) sampling frequency.

5.1 Analytical Parameters

A pattern can be seen from the thirteen-year water quality database. Some of the parameters have shown little or no change throughout the monitoring history, and some parameters respond in a pattern that is similar to others.

Analysis of the data is partially limited because of reporting and analytical procedures. The Method Detection Levels (MDLs) have changed throughout the history of the monitoring program. This situation makes trend analysis possible only in general terms. It also appears that anomalous data values have been left in the database, probably because of the reported difficulty to edit the VAX information.

The analytical parameters are organized into groups for this discussion. The groups are physical tests, metal analysis and inorganic tests. The data are further arranged as upgradient, ponds (surface water), downgradient (ground water), and downgradient (surface water). The sequence provides a generalized view of water quality changes associated with power plant activities.

5.1.1 Physical Tests

The nine physical tests performed for the current WQMP are shown on Table 6.

The field parameters (temperature, pH, and conductivity) are important indicator parameters. These parameters are used to evaluate if the collected water sample is representative of in-situ conditions and as an indicator of general water quality conditions.

The field temperature varies depending on the time of year and the depth of the well. Temperature ranges have been recorded from 2.0 to 26.0 degrees C. This temperature range is not unusual for these conditions. Temperature should be recorded as part of well sampling protocol but does not need to be presented as a primary WQMP indicator.

Field pH is especially useful to evaluate the potential mobility of metals in the soil and ground water. Metals are generally stable (immobile) when the pH is greater than 5.0, as is the case at this site. A typical range of pH in ground water is from 6.5 to 8.5. Laboratory pH is used to support the findings in the field and to document sample conditions in preparation for analysis.

Specific conductance is a measure of the waters ability to conduct an electrical current. The specific conductivity varies almost directly with the amount of dissolved minerals in the water. There is a strong correlation between total dissolved solids and specific conductance. For this reason, specific conductance and total dissolved solids (TDS) are useful indicators of water quality conditions. Total suspended solids (TSS) can be useful in evaluating natural surface water conditions. However, limited TSS data at this site and the presence of other surface water quality indicator parameters does not warrant inclusion of TSS in the WQMP.

Sewage from CCS is partially treated and then discharged to the Recycle Basin. Typical sewage indicator parameters are methylene blue active substances (MBAS), fecal coliform, and total coliform. The data, however, do not show a change in concentrations at the site. The only exception appears to be one sample in the River Water Holding Basin which shows non-fecal coliform which is probably related to the raw river water in the basin.

Based on the relationships discussed above, it is recommended that field pH, lab pH, specific conductance, and TDS be included in the revised WQMP. TSS, MBAS, fecal coliform, and total coliform are not necessary to monitor water quality trends at CCS or at the Falkirk disposal areas.

5.1.2 Metal Analysis

The 21 metal analyses performed for the current WQMP are shown on Table 6.

Metals that are expected to be present from coal ash are arsenic, boron, selenium, and strontium. These parameters show changes in concentrations and indicate that an impact to water quality has occurred. These parameters should continue to be monitored as part of the WQMP.

Barium, chromium, lead, and mercury are metals with established EPA maximum contaminant levels (MCL). These parameters, however, show relatively minor changes in concentration and are generally below the MCL for each parameter. It is recommended that these parameters be analyzed periodically (annually), but not reported as part of the permitted WQMP. The rationale is that if the primary indicator metals (arsenic, boron, selenium, and strontium) can be tracked and controlled, then the other metals will also be implicitly tracked and controlled without actually testing for them.

Aluminum, beryllium, cadmium, copper, molybdenum, nickel, and silver show relatively little changes in concentration, some of which is masked by the reported MDLs rather than measured concentrations. It is recommended that these parameters be analyzed periodically (annually), but not reported as part of the permitted WQMP. The rationale is that if the primary indicator metals (arsenic, boron, selenium, and strontium) can be tracked and controlled, then the other metals will also be implicitly tracked and controlled without actually testing for them.

Sodium, potassium, magnesium, manganese, and calcium are used internally for evaluating cation/anion balances. These parameters, however, do not need to be reported as part of the WQMP. The trends associated with these parameters are tracked by other parameters, notably TDS and specific conductance.

5.1.3 Inorganic Tests

The 10 inorganic tests performed for the current WQMP are shown on Table 6.

Sulfate and chloride are useful inorganic parameters for tracking ground water movement. Sulfate is released from the coal ash and is a recognizable ground water and surface water contaminant associated with power plant operations. Chloride is a very mobile parameter that indicates the probable maximum extent of other potential contaminants. Both of the parameters are found in elevated concentrations downgradient of the ponds and should be included in the WQMP.

Elevated fluoride and nitrate concentrations are reported. It is recommended that these parameters be analyzed periodically, but not reported as part of the WQMP. The basis for this statement is that other

mobile parameters are available for tracking and that at least the nitrate is not likely to be directly related to ash waste.

It is recommended that phenol, ammonia, total sulfur, biological oxygen demand (BOD), chemical oxygen demand (COD), and total organic carbon (TOC) not be tested or included in the WQMP. These parameters have a limited database, show uncertain trends, and can be indirectly evaluated by other parameters.

Bicarbonate alkalinity, carbonate alkalinity, and total alkalinity are used internally for evaluating cation/anion balances. These parameters, however, do not need to be reported as part of the WQMP. The trends associated with these parameters are tracked by other parameters, notably TDS and specific conductance.

5.1.4 Electromagnetics

An annual electromagnetic (EM) survey has been conducted since 1988 at Coal Creek Station and since 1989 at the FMDA. The principle of the geophysical technique is to measure the conductivity of the earth and its contents, including the ground water, so that a water quality pattern can be mapped. This survey was undertaken because the knowledge of the extent and magnitude of contamination was limited.

The EM survey has been useful to document the relationship between sulfate (a mobile and recognizable contaminant) and specific conductivity (a field measurement) versus electromagnetic values (electrical conductivity). The EM results at CCS supported the geological interpretation of areas of pond leakage and showed a widespread area of water quality impacts. EM was less successful in the FMDA because of (1) the geological complexities associated with mine operations and (2) the fact that the FMDA are clay lined engineered facilities that are not expected to allow recognizable leakage. Therefore it is recommended that EM surveys be discontinued in the FMDA.

EM work should be continued at CCS on a limited basis. EM data have been used as an indicator of water quality impacts between and beyond the monitoring well network. A baseline of EM values has been established which provides geological and water quality information. It is proposed that EM be used periodically to confirm the widespread effectiveness of the current and planned pond remediation program. Likely times for further EM surveys is Fall 1992 and Fall 1994. The 1992 program is intended to show the effects of repair at the completed ponds. This program will be compared with water quality data to verify correlation of water quality changes in the monitoring wells. The 1994 program is intended to document conditions after all of the ponds have been repaired. After 1994 it is anticipated that the

effectiveness of the pond remediation program can be evaluated based on selected monitoring wells and samples from the slough system.

The EM survey positions should be documented and maintained, however, for possible future use. For example, a suspected pond leak that is not well documented by the monitoring well network could be more accurately located by conducting an EM survey around the pond. This data could be compared to existing baseline data.

A summary of recommended parameter disposition is provided on Table 15. This list may be modified based on future data interpretation.

5.2 Sampling Locations

The number of sampling locations has increased throughout the site history. Most of the locations have remained in the monitoring network. A few have been deleted because (1) the monitoring well has been destroyed, (2) the surface water locations has dried up, and/or (3) special need locations, such as wells around the RWHB, are no longer needed. The current WQMP has 158 identified monitoring locations and many other locations that are not currently being monitored.

The current ground water and surface water locations are adequate to effectively monitor known water quality conditions. No new locations are anticipated. It is recommended that useful data points be maintained for current and future use. A list of key CCS ground water monitoring locations is provided on Table 16. It is recommended that other locations, such as the wells around the RWHB, be properly abandoned and removed (see Table 17). Damaged and/or redundant wells should also be repaired or abandoned.

Precipitation runoff sampling was conducted only in 1987. It is recommended that this requirement be formally deleted from the WQMP. However, the sampling locations will be maintained on inactive status in the event that future monitoring may be required.

A list of the known monitoring locations is presented in Tables 18, 19, and 20 for CCS-Ground Water, CCS-Surface Water, and FM-Ground Water, respectively. The tables identify the proposed disposition of each monitoring location.

5.3 Sampling Frequency

Sampling frequency has varied during the history of the power plant based on special needs. A more formal frequency was established with the 1986 WQMP and has continued with the current WQMP.

Now that a 13 year pattern of water quality trends has been established the frequency of sampling can be modified. An abbreviated program can be used to maintain documentation of the trends rather than a more intensive data collection program used primarily to establish a baseline of information. Completed and planned pond repairs have also minimized the need for extensive sampling.

It is proposed that the ground water and surface water sampling points be monitored for field parameters two times per year (2/yr) and that the laboratory parameters be analyzed one time per year (1/yr.) The sampling events should take place during consistently designated quarters each year. Sampling at CCS and FM may be conducted during different quarters, if desired. Table 21 illustrates this proposed schedule.

6.0 SUMMARY

This document provides an evaluation of the current Water Quality Monitoring Plan (WQMP) in terms of (a) analytical parameters, (b) sampling locations, and (c) sampling frequency. The primary purpose of this study is to provide a WQMP that is more cost effective and reflective of current needs. The evaluation is summarized below.

1. Known Conditions - An evaluation of the WQMP is appropriate and the recommendations are representative because of the following factors.

- Hydrogeological conditions (geology, water levels, and water flow direction) are well documented.

- An extensive network of monitoring locations is in place to document water quality conditions.

- Water quality and water level data have been collected at this site for 13 years.

2. Analytical Parameters - The list of reported analytical parameters has been reduced from 35 to 9 and is presented on Table 21. The revised list includes 3 physical tests, 4 metals, and 2 inorganic parameters.

The selected, reportable indicator parameters are generally easy to measure, mobile, and representative of general water quality conditions. The other water quality parameters that have been deleted from the primary list of parameters may be analyzed for internal reasons, such as QA/QC procedures, but are not necessary to be part of the formal reported WQMP. The identified indicator parameters are adequate to determine water quality conditions and to monitor additional actions, if necessary.

3. Sampling Locations - The current ground water and surface water locations are adequate to effectively monitor known water quality conditions. The list of the monitoring locations is reduced from 158 to 126. The program includes 95 CCS ground water locations, 7 CCS surface water locations, and 24 FM ground water locations, which are provided on Tables 22, 23, and 24, respectively.

This evaluation proposes that the monitoring network be continued and properly maintained. Unused, damaged, and/or redundant wells should be repaired or abandoned, as appropriate. No new locations are anticipated.

4. Sampling Frequency - A goal of this evaluation is to provide representative data that is reported in a timely manner and meets the needs of CCS and NDSDH. Because of the extensive existing data base, this goal can continue to be met with a modified sampling frequency schedule.

The proposed sampling frequency program includes sampling the Coal Creek Station (CCS) locations during a quarter that is different from sampling activities at the Falkirk Mine (FM) Disposal Areas. Furthermore, laboratory analysis of samples from CCS and FM will be one time per year, instead of two times per year. Field parameters will be recorded two times per year, instead of four times per year. The precipitation runoff sampling program is proposed to be deleted.

5. EM Survey - Electromagnetic (EM) surveys have been used to establish baseline geophysical conditions. This technique is useful to indirectly document water quality conditions.

It is recommended that the EM survey be performed at CCS in 1992 and 1994 to document the effects of the pond repair program. Additional EM surveys are not anticipated unless warranted by a specific need.

It is recommended that the EM program be discontinued in the Falkirk Mine Disposal Area. The data are inconclusive in this area because of geological complexities associated with mine operations. Furthermore, the clay lined engineered facilities are not expected to allow recognizable leakage.

7.0 REVISED WATER QUALITY MONITORING PLAN

The monitoring network and resultant data have increased during the past 13 years and have developed into a situation that is difficult to manage. Site operations and regulatory requirements have also changed. The revised WQMP has been developed to (1) meet the current site needs, (2) provide a cost-effective and representative monitoring program, and (3) establish a manageable database which can

be easily used by CCS ans NDSDH to track water quality changes. It is also intended that the revised WQMP be flexible and responsive to future needs.

The elements of the Revised Water Quality Monitoring Plan are outlined below.

- Ground Water Monitoring Locations - FM (Figure 7)

- Ground Water Monitoring Locations - CCS (Figure 8)

- Surface Water Monitoring Locations - CCS (Figure 9)

- Parameters and Frequency (Table 21)

- Sampling Locations (Tables 22, 23, & 24)

Appendix A
Coal Creek Station Investigative Reports

Sprg 1974 "Subsurface Investigation, Cooperative Power Association Coal Creek Station, Units 1 and 2, Exploratory Borings and Tests, Spring 1974" by Soil Exploration under the direction of Black and Veatch Consulting Engineers.

A total of 24 soil borings were completed to: 1) determine the extent of lignite deposits; 2) investigate and describe geology of the site; and 3) obtain data pertaining to engineering properties of soil and rock materials at the site.

Jan 1975 "Geotechnical Investigation Coal Creek Station," Vol. I & II by McClelland Engineers, Inc. for Black and Veatch Consulting Engineers 1975.

A total of 87 borings were completed to obtain geotechnical data for design and construction of an adequate and economical foundation for the power plant and associated facilities. The investigation included borings, obtaining soil samples for field and laboratory tests, installing piezometers and performing geotechnical analysis.

Jun 1975 "Test Borings for Well Construction," June 2, 1975 by Soil Exploration under the direction of Black and Veatch Consulting Engineers.

Seven test borings were completed to help locate potential aquifers and to determine depths to the Fort Union Formation. Report includes geophysical data performed by GeoScience Associates.

Sep 1977 Soil Investigation - "Ash Pond and Evaporation Pond Geotechnical Data," September 16, 1977, Soil Exploration under the direction of Black and Veatch Consulting Engineers.

A total of 72 soil borings were completed, 42 in the North Evaporation Pond and 31 in the East Ash Pond area, to obtain geotechnical data. Six of the borings were completed as piezometers at the East Ash Pond. Additional laboratory tests were run on selected soil samples from both areas.

Mar 1978 "South Ash Pond Geotechnical Data," March 3, 1978 by Soil Exploration under the direction of Black and Veatch Consulting Engineers.

A total of 15 soil borings were completed in the area of the proposed South Ash Pond. A series of geotechnical laboratory tests were performed on selected soil samples. Laboratory tests included permeability tests, Relative Density tests (modified proctor), sieve analysis, atterburg limits, triaxial test series and stress-stain curves.

Jan 1979 "Geotechnical Exploration Program, East Ash Pond and East Evaporation Pond, Coal Creek Station," January 16, 1979 by Soil Exploration under the direction of Black and Veatch Consulting Engineers.

A total of 27 soil borings were completed to determine geotechnical properties of soils in the areas of the proposed East Ash Pond and the proposed East Evaporation Pond.

May 1980 "East Ash Pond Liner Investigation" Coal Creek Station, May 19, 1980 by Black and Veatch Consulting Engineers.

A series of hand augers borings were performed at 200 foot intervals to determine the adequacy of the pond seal. Sand lenses were found to exist, hence effective ways to seal the pond were proposed. Supplementary borings were also completed along the inside perimeter of the dikes.

Oct 1980 "Piezometer Location Chart & Well Installation Observation & Locations for 10 through 23," October 14, 1980 by Soil Exploration under the direction of Black & Veatch Consulting Engineers.

No text. Charts, 6 construction diagrams, locations and boring logs for Piezometers 0-1 thru 0-23.

1980 "South Ash Pond Geotechnical Report" ~1980 by Black and Veatch Consulting Engineers.

Data was collected to determine the cause of seepage along the east and south dikes of the South Ash Pond. The study showed indications of seepage along the north, east and south dikes of the pond originating from within the pond.

Jan 1981 "Review of the South and East Ash Pond and the East Evaporation Pond," January, 1981 by Barr Engineering.

Seepage was observed in the South and East Ash Ponds and was evaluated by Barr Engineering. The East Evaporation Pond had not yet been filled but was predicated to seep if not modified. Alternatives for reduction of seepage was given for all three ponds.

Jun 1981 "Hydrogeologic Evaluation of Leakage From Ash and Evaporation Ponds at Coal Creek," June 1981 by Barr Engineering.

Conclusions were that there was a very high probability of significant seepage from the East Ash and East Evaporation Ponds. They proposed that additional studies be done on the ponds.

Jul 1981 "Geology & Hydrogeology of the East Evaporation Pond, Coal Creek Electrical Generating Station," July 8, 1981 by Stephen R. Moran of Barr Engineering.

A total of 18 soil borings and 22 test pits were completed in the East Evaporation Ponds. They found conditions in the south basin and at least half of the north basin would that warrant lining, with a low permeability clay liner. (Three options were given.)

Sep 1981 "Investigation for Clay Liner Materials East Evaporation Pond," September 1981, by Barr Engineering (For Cooperative Power Association and United Power Association).

An area north of the East Evaporation Ponds was investigated for importing clay material. An adequate amount of clay material was found or surmised to exist north and west of the pond for construction of the pond liner.

Apr 1982 "Coal Creek Station Surface Water Study," April 1982 by Barr Engineering.

The purpose of this study was to provide information regarding seepage from various ponds at Coal Creek. They estimated the amount and quality of the seepage that may occur from the North and East Evaporation Ponds, East and South Ash Ponds, and the River Extended Basins.

Jun 1982 "Coal Creek Station Surface Water Study", by Barr Engineering

June 1982 " Coal Creek Station Hydrogeologic Study", by Barr Engineering

Jun 1982 "Investigation for Clay Liner Materials, River Water Holding Basin," June 1982, by Barr Engineering.

Four borrow areas were examined for potential use for clay liner material. Three of the four areas were recommended as useful areas for clay liner material.

Jan 1984 "River Water Holding Basin Evaluation, Coal Creek Station," January, 1984, by Eugene A. Hickok and Associates.

The installation of 9 piezometers, 5 soil borings and analysis of available water level data was conducted to investigate boils observed along the west side of the River Water Holding Basin dike. The problem was defined and corrective action was recommended.

May 1985 "East Ash Pond Data Review," May 1985 by Eugene A. Hickok and Associates.

The East Ash Pond seepage rate was estimated at 2.2 million gallons per day. Geological conditions allow vertical seepage through the bottom of the pond and the east dike of the pond.

Aug 1985 "East Ash Pond Seepage Investigation," August 1985 by Eugene A. Hickok and Associates.

The study showed: 1) overall permeability of the East Ash Pond exceeds the criteria seepage rate; 2) the northerly one-third of the pond has a higher average permeability than the southerly two-thirds; and 3) repairing the pond would be necessary to meet seepage criteria.

Nov 1985 "Water Quality Monitoring Plan, Coal Creek Station for Cooperative Power Association and United Power Association," November, 1985 by Eugene A. Hickok and Associates.

The Water Quality Monitoring Plan established monitoring locations to evaluate potential water quality impacts to the wetlands and shallow ground water.

Jun 1986 "Monitoring Well Installation and Test Borings," June 27, 1986 by Twin City Testing.

A total of eight ground water monitoring wells were installed to supplement the existing wells in the area of the South and East Ash Ponds. The wells are designated MW-40 thru MW-47.

Jul 1986 "Evaluation of Pond Bottom Conditions Southwest and West Portions of the East Ash Pond, Coal Creek Station," July, 1986 by Eugene A. Hickok and Associates.

Conclusions were made that the low area was excavated replacing clay-rich material with an unknown material having limited compaction. Permeability tests in fill area are not representative of the pond bottom soil conditions.

Dec 1988 "Geophysical Survey Results at Coal Creek Station",
December 20, 1988, by Minnesota Geophysical Associates, Inc.

Mar 1989 "Hydrogeological Analysis for Coal Creek Station," March, 1989 by Foth & Van Dyke.

A total 21 monitoring wells and seven borings were completed to: 1) evaluate hydrogeological characteristics for the design considerations of the South Ash Pond; 2) evaluate the potential need for remediation at the Recycle Basin; and 3) define a potential clay rich borrow area southwest of the South Ash Pond.

Oct 1989 "Drilling Data - Summer 1989, Cooperative Power Association and United Power Association," October 1989, by Foth & Van Dyke.

A total of 141 soil borings and 26 monitoring wells were completed to provide information in or around the North Evaporation Ponds, East Evaporation Ponds and the South Ash Pond. Borings were completed on the pond bottoms and dikes

for the North and East Evaporation Ponds and Southwest of the South Ash Pond. Monitoring wells were completed throughout the site.

Nov 1989 "Geophysical Survey Results at Coal Creek Power Station," November 15, 1989 by Minnesota Geophysical Associates, Inc.

The survey measured the change in conductivity since the baseline survey was performed in November 1988. It established new baseline data around the North and East Evaporation Ponds and to the west of the South Ash Pond. The data will be used to determine the possible extent, direction and pattern of containment migration in the area.

Nov 1990 "Geophysical Survey Results, Coal Creek Station and Falkirk Mine," November 1990, by Geosphere Midwest.

A geophysical survey consisting of a series of electromagnetic induction profiles was conducted to detect variations in levels of ground water contamination adjacent to the South and East Ash Ponds, the North and East Evaporation Ponds and three ash pits associated with the Falkirk mine. This study showed a small, uniform decrease in apparent conductivities over the entire area, probably due to increased rainfall in 1990 over 1989. No other conclusions could be drawn from this study.

Dec 1990 "On-Site Borrow Investigation," December 13, 1990 by Braun Engineering.

A total of five soil borings were completed in the area of section 8 to determine its suitability as a borrow location for clay lining of ponds. A suitable lean clay was encountered at all locations, however impurities such as trace sand, gravel or lignite were also present.

Dec 1990 "Hydrogeological Analysis Annual Report," December 21, 1990 by Braun Engineering.

This report includes data summary tables and graphs of selected available data as well as a narrative discussion of water quality, in the areas of the evaporation and disposal ponds, to meet permit requirements set by the State of North Dakota.

Dec 1990 "Hydrogeological Analysis, East Evaporation Ponds Coal Creek Station," December 21, 1990 by Braun Environmental Laboratories.

This Hydrogeologic Analysis evaluated geological and hydrogeological data to develop geologic cross-sections to determine a design elevation for the pond bottom.

- "Ground Water Resources Near Max, McLean and Ward Counties, North Dakota, N.D. Ground Water Studies No. 45" by the U.S. Geological Survey, N.D. State Water Commission and N.D. Geological Survey.

A 64 square mile area was investigated for geologic reconnaissance, test drilling, well inventory and collection of water samples for chemical analysis.

- "North Dakota State Department of Health, Bacteriological Water Analysis." Unknown date and author.

A summary of nearby and on-site production wells water analysis report and bacteriological water analysis report.

- Application to Renew Permit to Operate Special Use Disposal Site, Coal Creek Station, Permit #SU-033.

Mar 1988 Liner Evaluation South Ash Pond and East Ash Pond Coal Creek Station, McLean County, North Dakota. March, 1988.

Dec 1989 Hydrogeological Analysis for the North Evaporation Ponds, Coal Creek Station, McLean County, North Dakota. December, 1989.

Nov 1987 South Ash Pond Evaluation, Coal Creek Station. November, 1987.

Appendix B
Falkirk Mine Investigative Reports

Apr 1979 "Falkirk Mine Underwood, North Dakota Report of Regional Ground Water Modeling Studies, Section XI-F, Amendment to Permit 40" by Peter J. Riordan P.E. Consulting Engineer and Ground water Hydrologist, April 1979.

The study indicated that the proposed mining operations would have minimal to no impact on ground water quantity in the town of Underwood. Also, no long-term impacts on the regional flow system are foreseen.

Nov 1985 "Water Quality Monitoring Plan, Coal Creek Station for Cooperative Power Association and United Power Association," November, 1985 by Eugene A. Hickok and Associates.

The Water Quality Monitoring Plan established monitoring locations to evaluate potential water quality impacts to the wetlands and shallow ground water.

Jan 1990 "Geophysical Survey Results at the Falkirk Mine," January 5, 1990 by Minnesota Geophysical Associates, Inc.

Areas of high conductivity were detected, possibly due to sulfate contamination. Baseline EM data were established so future surveys could measure changes in contamination levels. EM conductivity data were obtained at 12 monitoring well locations, allowing correlation between geophysical and well sample data.

Nov 1990 "Geophysical Survey Results, Coal Creek Station and Falkirk Mine," November 1990, by Geosphere Midwest.

A geophysical survey consisting of a series of electromagnetic induction profiles was conducted to detect variations in levels of ground water contamination adjacent to the South and East Ash Ponds, the North and East Evaporation Ponds and three ash pits associated with the Falkirk mine. This study showed a small, uniform decrease in apparent conductivities over the entire area, probably due to increased rainfall in 1990 over 1989. No other conclusions could be drawn from this study.

- "Ground Water Resources Near Max, McLean and Ward Counties, North Dakota, N.D. Ground Water Studies No. 45" by the U.S. Geological Survey, N.D. State Water Commission and N.D. Geological Survey.

  A 64 square mile area was investigated for geologic reconnaissance, test drilling, well inventory and collection of water samples for chemical analysis.

COAL CREEK STATION
WATER QUALITY MONITORING PROGRAM
FIRST QUARTER 1991

Coal Creek Station's groundwater and surface water sampling program to be performed during the first quarter of 1991.

GROUNDWATER SAMPLING PROGRAM

Wells to be sampled:

* Section 5 Disposal Area wells: 501, 523-525, 531-542.
* Section 31 Disposal Area wells: 543-544, 546-549.
* Section 32 Disposal Area wells: 550-555.

Surface waters to be sampled:

* Surface waters 601-602.

Field data to be collected:

* Sample period.
* Date pre-pumped.
* Volume pre-pumped.
* Date sampled.
* Water level depth below ground surface.
* Weather conditions.
* Sample ph, temperature, and specific conductance.
* Sample collection technique, (Bailer or Bladder Pump).
* Additional comments.

Laboratory Analysis for all samples:

* Physical tests: ph, specific conductance, TDS.
* Metal analysis: Mg,K,Na,Ca,B,Fe,Mn,Sr,Se,As,Cd.
* Inorganic tests: Total Alk,SO4,NO3-N,Total S,F,Cl.

SNOW-MELT SAMPLING PROGRAM

In the event of significant snowfall/rainfall and run-off the following samples should be taken.

Locations to be sampled:

* Sample location: 401 - 409.

Field data to be collected:

* Sample period.
* Date sampled.
* Weather Conditions.
* Sample ph, temperature, specific conductance.
* Additional comments.

Laboratory analysis for all samples:

* Physical tests: ph, specific conductance, TDS, TSS.
* Metal analysis: Mg, K, Na, Ca, B, Fe, Mn, Sr, Se, As, Cd.
* Inorganic tests: Total Alk, SO4, NO3-N, Total S, F, Cl.

COAL CREEK STATION
WATER QUALITY MONITORING PROGRAM
SECOND QUARTER 1991

Coal Creek Station's groundwater and surface water sampling program to be performed during the second quarter of 1991.

GROUNDWATER AND SURFACE WATER SAMPLING PROGRAM

Wells to be sampled:

* Section 5 Disposal Area wells: 501, 523-525, 531-542.
* Section 31 Disposal Area wells: 543-544, 546-549.
* Section 32 Disposal Area wells: 550-555.
* CCS monitoring wells 1-94
* HPZ wells 8 and 9
* Observation well 023

Surface waters to be sampled:

* Surface waters 101-105, 107-127, 601-602.

Field data to be collected:

* Sample period.
* Date pre-pumped.
* Volume pre-pumped.
* Date sampled.
* Water level depth below ground surface.
* Weather conditions.
* Sample ph, temperature, and specific conductance.
* Sample collection technique, (Bailer or Bladder Pump).
* Additional comments.

Laboratory Analysis for all samples:

* Physical tests: ph, specific conductance, TDS.
* Metal analysis: Mg,K,Na,Ca,B,.
* Inorganic tests: Total Alk,SO4,F,Cl.

Additional analysis:

* Fe: MW 69-94, 501, 523-525, 531-542, 543-549, 550-555.
* Mn: MW 69-94. 501, 523-525, 531-542, 543-549, 550-555.
* Sr: MW 69-94, 501, 523-525, 531-542, 543-549, 550-555.
* Se: MW 31, 32, 37, 69-94, 501, 523-525, 531-542, 543-549, 550-555,
* As: MW 32, 45, 69-94, 501, 523-525, 531-542, 543-549, 550-555, SW 105, 108, 112-117, 119-122, 125-127.
* Cd: MW 8, 69-94, 501, 523-525, 531-542, 543-549, 550-555.
* Total S: MW 69-94, 501, 523-525, 531-542, 543-549, 550-555.
* NO3-N: MW 69-94, 501, 523-525, 531-542, 543-549, 550-555, SW 101-105, 107-127.
* Al: MW 44.

COAL CREEK STATION
WATER QUALITY MONITORING PROGRAM
THIRD QUARTER 1991

Coal Creek Station's groundwater and surface water sampling program to be performed during the third quarter of 1991.

GROUNDWATER SAMPLING PROGRAM

Wells to be sampled:

* Section 5 Disposal Area wells: 501, 523-525, 531-542.
* Section 31 Disposal Area wells: 543-544, 546-549.
* Section 32 Disposal Area wells: 550-555.

Surface waters to be sampled:

* Surface waters 601-602.

Field data to be collected:

* Sample period.
* Date pre-pumped.
* Volume pre-pumped.
* Date sampled.
* Water level depth below ground surface.
* Weather conditions.
* Sample ph, temperature, and specific conductance.
* Sample collection technique, (Bailer or Bladder Pump).
* Additional comments.

Laboratory Analysis for all samples:

* Physical tests: ph, specific conductance, TDS.
* Metal analysis: Mg,K,Na,Ca,B,Fe,Mn,Sr,Se,As,Cd.
* Inorganic tests: Total Alk,SO4,NO3-N,Total S,F,Cl.

COAL CREEK STATION
WATER QUALITY MONITORING PROGRAM
FOURTH QUARTER 1991

Coal Creek Station's groundwater and surface water sampling program to be performed during the fourth quarter of 1991.

GROUNDWATER AND SURFACE WATER SAMPLING PROGRAM

Wells to be sampled:

* Section 5 Disposal Area wells: 501, 523-525, 531-542.
* Section 31 Disposal Area wells: 543-544, 546-549.
* Section 32 Disposal Area wells: 550-555.
* CCS monitoring wells 1-94
* HPZ wells 8 and 9
* Observation well 023

Surface waters to be sampled:

* Surface waters 101-105, 107-127, 601-602.

Field data to be collected:

* Sample period.
* Date pre-pumped.
* Volume pre-pumped.
* Date sampled.
* Water level depth below ground surface.
* Weather conditions.
* Sample ph, temperature, and specific conductance.
* Sample collection technique, (Bailer or Bladder Pump).
* Additional comments.

Laboratory Analysis for all samples:

* Physical tests: ph, specific conductance, TDS.
* Metal analysis: Mg,K,Na,Ca,B,.
* Inorganic tests: Total Alk,SO4,F,Cl.

Additional analysis:

* Fe: MW 69-94, 501, 523-525, 531-542, 543-549, 550-555.
* Mn: MW 69-94. 501, 523-525, 531-542, 543-549, 550-555.
* Sr: MW 69-94, 501, 523-525, 531-542, 543-549, 550-555.
* Se: MW 31, 32, 37, 69-94, 501, 523-525, 531-542, 543-549, 550-555,
* As: MW 32, 45, 69-94, 501, 523-525, 531-542, 543-549, 550-555, SW 105, 108, 112-117, 119-122, 125-127.
* Cd: MW 8, 69-94, 501, 523-525, 531-542, 543-549, 550-555.
* Total S: MW 69-94, 501, 523-525, 531-542, 543-549, 550-555.
* NO3-N: MW 69-94, 501, 523-525, 531-542, 543-549, 550-555, SW 101-105, 107-127.
* Al: MW 44.

Yearly QA Split to Contract Lab

Monitoring wells 7,8,13,14,15.

* Specific Conductance, TDS.
* Mg, K, Ca, B.
* Alk (Total, Carbonate, Bicarbonate), SO4, F, Cl.
* NO3-N, Fe, Mn, Sr, As, Al.

COAL CREEK STATION
WATER QUALITY MONITORING PROGRAM
FIVE YEAR SAMPLE SCHEDULE

Coal Creek Station's groundwater and surface water sampling program to be performed during the _____ quarter of 19__.

GROUNDWATER AND SURFACE WATER SAMPLING PROGRAM

Wells to be sampled:

* Section 5 Disposal Area wells: 501, 523-525, 531-542.
* Section 31 Disposal Area wells: 543-544, 546-549.
* Section 32 Disposal Area wells: 550-555.
* CCS monitoring wells 1-5,7-18, 20-24, 26-94.
* HPZ wells 8 and 9
* Observation well 023

Surface waters to be sampled:

* Surface waters 101-105, 107-127, 601-602.

Field data to be collected:

* Sample period.
* Date pre-pumped.
* Volume pre-pumped.
* Date sampled.
* Water level depth below ground surface.
* Weather conditions.
* Sample ph, temperature, and specific conductance.
* Sample collection technique, (Bailer or Bladder Pump).
* Additional comments.

Laboratory Analysis for all samples:

* Physical tests: ph, specific conductance, TDS.
* Metal analysis: Mg,K,Na,Ca,B,.
* Inorganic tests: Alk(Total,Carbonate,& Bicarbonate),SO4,F,Cl.

Additional analysis for all Wells and Surface Waters:

* NO3, Fe, Zn, Mn, Cu, Ag, Sr, Be, Ni, Se, Hg, As, Ba, Cd, Cr, Pb, Mo, Al, Total S.

Additional Special Analysis for Surface Waters 104,113,114,126,127:

* TSS

Contract Lab Analysis

Surface waters 101-103, 115-118, 120-124:

* MBAS, Total Coliform, Fecal Coliform.

Surface waters 104,113,114,126,127:

* BOD, COD, TOC, NH3-N.

Surface water 102, Monitoring wells 9 & 10.

* Phenol

Yearly QA Split to Contract Lab

Monitoring wells 7,8,13,14,15.

* Specific Conductance, TDS.
* Mg, K, Na, Ca, B.
* Alk (Total, Carbonate, Bicarbonate), SO4, F, Cl.
* NO3-N, Fe, Mn, Sr, As, Al, Ba, Mo, Pb, Cr-Total, Se, Cd, Ni.

Legend:
--, not analyzed
ft AMSL, feet above mean sea level
mg/L, milligrams per liter
s.u., standard units for pH
pCi/L, picocuries per liter

Laboratory Provided Qualifiers:
^ (samples prior to June 2018) = Reporting limit elevated due to instrument performance at the lower limit of quantification (LLOQ).
U (general chemistry) = Not detected above the shown practical quantitation limit
U (radiochemistry) = Result is less than the sample detection limit (varies by sample)
^ (samples after June 2018) = ICV, CCV, ICB, CCB, ISA, ISB, CRI, CRA, DLCK, or MRL standard: Instrument related QC is outside acceptance limits.

Notes:
Samples collected prior to June 2018 were analyzed by Minnesota Valley Testing Laboratories, with radiochemical analysis subcontracted to Intermountain Laboratories.
Samples collected from June 2018 to present were analyzed by Eurofins TestAmerica Laboratories.
In changing analytical laboratories, some differences have been noted in analytical methodologies and associated reporting limits. Methods used are EPA-approved.
Non-detects have been listed at the reported practical quantitation limit.
Metal results represent the total concentration (i.e. samples have not been filtered).
Precision was not recorded for samples with radiological concentrations below the reporting limit by Intermountain Laboratories for Radium-226 samples reported using SM 7500 Ra-B or Radium-228 samples reported using the Georgia Tech method.
Radium-226 and -228 combined has been reported as the calculated sum of Radium-226 and Radium-228 results, or the reporting limit for non-detect results.

Laboratory Provided Qualifiers:
^ (samples prior to June 2018) = Reporting limit elevated due to instrument performance at the lower limit of quantification (LLOQ).
U (general chemistry) = Not detected above the shown practical quantitation limit
U (radiochemistry) = Result is less than the sample detection limit (varies by sample)
^ (samples after June 2018) = ICV, CCV, ICB, CCB, ISA, ISB, CRI, CRA, DLCK, or MRL standard: Instrument related QC is outside acceptance limits.

Notes:
Samples collected prior to June 2018 were analyzed by Minnesota Valley Testing Laboratories, with radiochemical analysis subcontracted to Intermountain Laboratories.
Samples collected from June 2018 to present were analyzed by Eurofins TestAmerica Laboratories.
In changing analytical laboratories, some differences have been noted in analytical methodologies and associated reporting limits. Methods used are EPA-approved.
Non-detects have been listed at the reported practical quantitation limit.
Metal results represent the total concentration (i.e. samples have not been filtered).
Precision was not recorded for samples with radiological concentrations below the reporting limit by Intermountain Laboratories for Radium-226 samples reported using SM 7500 Ra-B or Radium-228 samples reported using the Georgia Tech method.
Radium-226 and -228 combined has been reported as the calculated sum of Radium-226 and Radium-228 results, or the reporting limit for non-detect results.
An additional sample was collected at MW-91-2 in September 2019, after the June 2019 sample was found to have been switched with the sample from MW-91-1. Analytical results from both events are provided for informational purposes.

Precision was not recorded for samples with radiological concentrations below the reporting limit by Intermountain Laboratories for Radium-226 samples reported using SM 7500 Ra-B or Radium-228 samples reported using the Georgia Tech method.
Radium-226 and -228 combined has been reported as the calculated sum of Radium-226 and Radium-228 results, or the reporting limit for non-detect results.

Legend:
--, not analyzed
ft AMSL, feet above mean sea level
mg/L, milligrams per liter
s.u., standard units for pH
pCi/L, picocuries per liter

Laboratory Provided Qualifiers:
^ (samples prior to June 2018) = Reporting limit elevated due to instrument performance at the lower limit of quantification (LLOQ).
U (general chemistry) = Not detected above the shown practical quantitation limit
U (radiochemistry) = Result is less than the sample detection limit (varies by sample)
^ (samples after June 2018) = ICV, CCV, ICB, CCB, ISA, ISB, CRI, CRA, DLCK, or MRL standard: Instrument related QC is outside acceptance limits.
H = Sample was prepped or analyzed beyond the specified holding time.

Notes:
Samples collected prior to June 2018 were analyzed by Minnesota Valley Testing Laboratories, with radiochemical analysis subcontracted to Intermountain Laboratories.
Samples collected from June 2018 to present were analyzed by Eurofins TestAmerica Laboratories.
In changing analytical laboratories, some differences have been noted in analytical methodologies and associated reporting limits. Methods used are EPA-approved.
Non-detects have been listed at the reported practical quantitation limit.
Metal results represent the total concentration (i.e. samples have not been filtered).
Precision was not recorded for samples with radiological concentrations below the reporting limit by Intermountain Laboratories for Radium-226 samples reported using SM 7500 Ra-B or Radium-228 samples reported using the Georgia Tech method.
Radium-226 and -228 combined has been reported as the calculated sum of Radium-226 and Radium-228 results, or the reporting limit for non-detect results.

Legend:
--, not analyzed
ft AMSL, feet above mean sea level
mg/L, milligrams per liter
s.u., standard units for pH
pCi/L, picocuries per liter

Laboratory Provided Qualifiers:
^ (samples prior to June 2018) = Reporting limit elevated due to instrument performance at the lower limit of quantification (LLOQ).
@ = Analyte required a dilution due to sample matrix, resulting in an elevated RL.
U (general chemistry) = Not detected above the shown practical quantitation limit
U (radiochemistry) = Result is less than the sample detection limit (varies by sample)
^ (samples after June 2018) = ICV, CCV, ICB, CCB, ISA, ISB, CRI, CRA, DLCK, or MRL standard: Instrument related QC is outside acceptance limits.
H = Sample was prepped or analyzed beyond the specified holding time.

Notes:
Samples collected prior to June 2018 were analyzed by Minnesota Valley Testing Laboratories, with radiochemical analysis subcontracted to Intermountain Laboratories.
Samples collected from June 2018 to present were analyzed by Eurofins TestAmerica Laboratories.
In changing analytical laboratories, some differences have been noted in analytical methodologies and associated reporting limits. Methods used are EPA-approved.
Non-detects have been listed at the reported practical quantitation limit.
Metal results represent the total concentration (i.e. samples have not been filtered).
Precision was not recorded for samples with radiological concentrations below the reporting limit by Intermountain Laboratories for Radium-226 samples reported using SM 7500 Ra-B or Radium-228 samples reported using the Georgia Tech method.
Radium-226 and -228 combined has been reported as the calculated sum of Radium-226 and Radium-228 results, or the reporting limit for non-detect results.

TABLES

Table 1: CCR Constituent Lists 2

1.0 INTRODUCTION

Golder Associates Inc. (Golder) has prepared this revision to the Coal Combustion Residuals (CCR) Groundwater Statistical Method Certification Report on behalf of Great River Energy (GRE) to certify that the statistical methodology to be employed at GRE's Coal Creek Station (CCS) is appropriate and meets the requirements of 40 CFR 257.93 (f) and (g).

1.1 Purpose

The CCR rule establishes specific requirements for statistical analysis of groundwater monitoring networks in 40 CFR 257.93 (Groundwater sampling and analysis requirements). Per part (f) of § 257.93, owners or operators of CCR units must select a statistical method to evaluate groundwater monitoring data for the constituents specified in Appendix III and Appendix IV of the rule. This report serves as the documentation of the required certification of the selected statistical methodology, in accordance with 40 CFR 257.93(f)(6).

This document may be periodically revised based on a review of changes to guidance documents provided by the United States Environmental Protection Agency (USEPA) or other governing entities, as well as revisions to the language of the rule itself.

1.2 Site Background

Coal Creek Station is located in McLean County, approximately 10 miles northwest of Washburn, North Dakota. CCS has four CCR facilities regulated under the CCR rule. The CCR units include the following:

- Drains Pond System CCR Surface Impoundment (Drains Pond System)
- Upstream Raise 91 CCR Surface Impoundment (Upstream Raise 91)
- Upstream Raise 92 CCR Surface Impoundment (Upstream Raise 92)
- Southeast Section 16 CCR Landfill (Southeast 16)

1.3 Constituents

Baseline samples (a minimum of eight) are collected for each well within the system and analyzed for both Appendix III and Appendix IV constituent lists associated with the CCR rule (Table 1). Additionally, the following field parameters are recorded: pH, specific conductivity, turbidity, and temperature. Following collection of baseline samples, semi-annual detection monitoring samples will be analyzed for the Appendix III constituent list and field parameters. If assessment monitoring is required, samples will be analyzed for the Appendix IV constituent list in accordance with CCR rule requirements. During the baseline period and all subsequent samples collected as part of the CCR sampling program, metals will be analyzed as total recoverable metals, i.e., samples will not be filtered.

The statistical analyses described in the following sections will be performed for each of the Appendix III constituents listed in Table 1 during detection monitoring, and for the Appendix IV constituents in the event of assessment monitoring. Apart from field pH, statistical analysis will not be conducted on field constituents (specific conductivity, turbidity, and temperature). There is a high potential for false positive results with field measurements due to sample collection inconsistency (e.g., changes in field conditions and sampling personnel), equipment calibration variability, and other causes of measurement variability.

Table 1: CCR Constituent Lists

Appendix III Constituents	Appendix IV Constituents
Boron	Antimony
Calcium	Arsenic
Chloride	Barium
Fluoride	Beryllium
pH (Field)	Cadmium
Sulfate	Chromium
Total Dissolved Solids (TDS)	Cobalt
	Fluoride
	Lead
	Lithium
	Molybdenum
	Radium-226 and -228 Combined
	Selenium
	Thallium

2.0 STATISTICAL METHODOLOGY

The purpose of groundwater monitoring in conjunction with the CCR rule is to determine if the regulated CCR Units are impacting groundwater. To determine if an impact has occurred, recent groundwater data from each well will undergo statistical analysis. The statistical methodology outlined within this document was selected in accordance with 40 CFR 257.93 of the CCR rule and the *Statistical Analysis of Groundwater Monitoring Data at RCRA Facilities, Unified Guidance* (Unified Guidance, USEPA 2009). Additional consideration was given to recommendations prepared by the Electric Power Research Institute (EPRI 2015).

Baseline diagnostic tests will be conducted using baseline samples collected at each well. Statistical analysis will be conducted using Sanitas (Sanitas Technologies 2014) or similar statistical analysis software.

During detection monitoring, comparative statistical analysis will be performed after each monitoring event to identify whether concentrations are potentially statistically significant in comparison to baseline values. The results will be reported annually. If assessment monitoring is conducted, comparative statistical analysis will be conducted following the collection of the specified number of confirmation samples.

The baseline data for all constituents, as determined by the monitoring program, will be reviewed periodically (approximately every 2 to 3 years based on a semi-annual sampling frequency during detection monitoring) to determine if recent results that are not statistically significant in comparison to baseline values can be incorporated into an updated baseline period (specifics of the baseline update procedure are discussed in depth in Section 2.2.6).

2.1 Intra-Well Methodology

Intra-well (comparing compliance data to baseline data within a single well) statistics are identified as an appropriate method for groundwater monitoring at CCS. This method is based on the following factors outlined in the Unified Guidance (USEPA 2009).

- Per the Unified Guidance: “Intra-well methodology allows establishment of reasonable baseline period for future tests in historically impacted wells. Additionally, measurements occur solely between the baseline period and compliance period of testing within a single well.”
  - Past CCR depositional facilities are known to have impacted the subsurface hydrology. Those facilities have been removed and new facilities with engineered lining systems constructed. The use of intra-well statistics allows future potential changes in water chemistry to be more readily tracked in relation to current CCR facilities at CCS.
- Per the Unified Guidance: “Confounding results stemming from spatial variability can be eliminated.”
  - Due to the heterogeneity of the glacial geology at CCS, spatial variability is displayed throughout the groundwater monitoring network. Use of intra-well statistics allows comparisons to be made on a per well basis, which avoids comparisons being made in differing geologic/geochemical conditions.

2.2 Methodology for Baseline Diagnostic Tests

2.2.1 Initial Data Review and Non-detect Handling

Initially, data will be plotted on time-series graphs to assess the temporal variability of the data and to visually screen for potential outliers. Temporal variability can be caused by seasonality, changes to the monitored system, changes to the analytical method, recalibration of instruments, and anomalies in the sampling method (USEPA 2009).

Non-detect values (ND) are results where the constituent is not detected at a concentration above the Practical Quantitation Limit (PQL). The PQL is the lowest concentration that can be reliably measured within the specified limits of precision and accuracy during routine laboratory operating conditions. ND values will be managed following the approach recommended by the Unified Guidance (USEPA 2009):

- For sample populations with < 15% ND, direct substitution of the NDS with ½ the PQL.
- For sample populations with 15% < ND ≤ 50%, the Kaplan-Meier approach will be used to estimate the mean and standard deviation of the population.
- For sample populations with > 50% ND, non-parametric approaches will be used to assess the data, with direct substitution of the NDs with the PQL.

2.2.2 Data Distribution

Parametric statistical tests are based on the assumption that the data are normally-distributed or can be transformed to a normal distribution. The distribution of the data will be tested for normality using the Shapiro-Wilk normality test with at 95 percent confidence level (or the Shapiro-Francia test when there are more than 50 results within the dataset). Each constituent from each well will be analyzed separately. Datasets found to be non-normal will be tested for other distributions using the 'Ladder of Powers' described by the Unified Guidance and transformed accordingly. Following transformation, parametric statistical methods will be performed on the normally or transform-normally distributed data. Non-parametric statistics will be used for datasets that do not show normal or transform-normal distributions, or for populations with greater than 50% ND.

2.2.3 Outlier Analysis

In accordance with the Unified Guidance, data points will be identified as outliers if the value was an "extreme, unusual-looking measurement" and "inconsistent with the distribution of the remaining measurements." The Unified Guidance recommends testing for outliers within baseline data, but cautions against removal of outliers, unless a likely error or specific discrepancy can be identified, such as recordkeeping errors, unusual procedures or conditions during sampling or at the laboratory, inconsistent sample turbidity, or values significantly outside the range of other results. In accordance with the Unified Guidance, apparent outliers will be periodically revisited even if initially removed, due to the propensity of groundwater chemistry to change over time.

Outliers will be evaluated and identified through visual inspection and the USEPA-recommended Dixon's Test for statistical outliers (or Rosner's Test when there are greater than 25 samples). Dixon's and Rosner's Tests assume that all data values, except the suspected outlier, are normally distributed or can be transformed to fit a normal distribution. Consequently, visual inspection of concentrations over time is important in screening for outliers. The effect of removing outliers from the baseline data will usually be to lower statistical limit (due to a reduction in the standard deviation of the dataset), resulting in a more conservative statistical limit and improving the odds of detecting increasing concentration levels.

Outliers will be managed as follows:

- Any suspected outliers identified through statistical analysis or visual methods will be reviewed (i.e., through evaluation of the associated analytical report, laboratory narrative, associated laboratory quality assurance/quality control information, and/or field notes) before removal from the dataset to determine if any systematic or systemic errors were responsible for the noted anomalous readings. Rejected data points will not be included in the baseline dataset.
- The rationale for the removal of any outliers will be documented. The majority of outliers will likely be isolated values that can be attributed to inconsistent sampling or analytical chemistry methodology resulting in laboratory contamination or other anomalies.
- If an outlier is removed, the normality test (Section 2.2.2) will be re-run to determine if the dataset is normally-distributed or transform-normal without the outlier.

2.2.4 Trend Analysis

Most statistical tests assume concentrations do not demonstrate temporal correlation. The Sen's Slope methodology is an intra-well statistical analysis of increases or decreases in measured concentrations over time measured by calculating the slope of the linear relationship of concentration levels and time. Sen's Slope Methodology is paired with the Mann-Kendall test to determine the statistical significance of the calculated Sen's

Slope. The methodology involves examining all possible pairs of measurements in the dataset and scoring each pair to determine if a trend exists. The test will be conducted using a target confidence level of 99 percent.

If temporal trends are identified within the dataset, the data will be adjusted to account for the trends, the time period used for the baseline statistics will be reassessed, and/or an alternative statistical method will be used to establish a limit. In the case of downward trends, no adjustments may be considered appropriate and a particular constituent may not be considered for statistical analysis until further data is collected.

2.2.5 Seasonality

Seasonal temporal variability can mask changes in groundwater chemistry. Time-series plots will be observed for visual signs of seasonality, and once enough data has been collected within the program, the data will be evaluated for seasonal variations using the seasonal Mann-Kendall trend test. The Mann-Kendall test is an intra-well evaluation performed individually for each constituent at each well and requires at least 3 occurrences of each prospective season with results to calculate the statistic. Datasets that are found to have seasonality will be de-seasonalized for subsequent statistical analysis.

2.2.6 Updating the Baseline Period

The Unified Guidance recommends updating the baseline period every two to three years when sampling frequency is semi-annual, or every four to eight collected samples. A baseline update will include a review of any revisions to federal and state regulations and USEPA statistical guidance documents that may have been promulgated since the previous baseline statistical analysis. The baseline period for a specific constituent will not be updated if verified statistically significant increases (SSIs) have been identified for that constituent, unless a demonstration has been made that the SSI is not related to a release from the facility.

Prior to inclusions of more recent data in an updated baseline period, a Wilcoxon Rank-Sum test will be conducted. The Wilcoxon Rank-Sum test, also referred to as the Mann-Whitney test, determines if measurements from one population are statistically significantly higher or lower than another population. The test is non-parametric, namely the data being tested are not assumed to fit a specific distribution, such as a normal distribution. When the baseline period is updated in the future, the Wilcoxon Rank-Sum test will be used to compare data from the current baseline period with the more recent data that are intended to be reclassified and included in the updated baseline period. The test will be conducted at a 95 percent confidence level. If the two datasets are drawn from the same population, then the results of the test support updating the prior baseline data set with the recent data. After the new data are incorporated into the dataset, the baseline diagnostic tests outlined in Section 2.2 will be conducted.

If the Wilcoxon Rank-Sum test detects a significant difference between two sample populations, additional data review will be necessary. The data will be reviewed to determine whether a gradual trend or other change not stemming from a release from the facility has occurred that was not detected during comparative statistical analysis. At the time of the baseline update, some earlier baseline data might need to be removed from the updated baseline period. Removal of earlier baseline data ensures that future statistical analysis is based on current groundwater conditions, rather than on outdated measurements of groundwater chemistry. Alternatively, outliers identified in the previous baseline period (as described in Section 2.2.3) will be re-incorporated into the dataset and reevaluated as potential outliers during the baseline update, unless the outlier(s) were removed due to sampling, laboratory, or other determinant error.

3.0 DETECTION MONITORING

3.1 Statistical Limits

Either a parametric or non-parametric method will be used to generate the baseline statistical limit for each constituent. The statistical method may vary between constituents and will be selected based on the percent of ND values in the baseline period and the baseline data distribution for each constituent at each well, in accordance with the Unified Guidance (USEPA 2009).

For those constituent-well pairs where concentrations of a given analyte are normally or transform-normally distributed and have equal to or greater than 50% detections, Shewhart-CUSUM control charts will be used. The Unified Guidance notes that Shewhart-CUSUM control charts use two separate evaluation procedures. The Shewhart portion is similar to a parametric prediction limit, comparing compliance measurements to a baseline limit. The CUSUM (cumulative summation) portion of the test analyzes new measurements against prior compliance measurements. The mean ($\bar{x}$) and standard deviation (s) of the baseline dataset are used to calculate the limit, by the following equation:

$$\bar{x}_{BG} + hs_{BG}$$

Per the Unified Guidance, h is the standardized control limit.

Where the concentrations of a given constituent-well pair are not normally or transform-normally distributed, or contain less than or equal to 50% detections, a non-parametric prediction limit will be used. The non-parametric limit will be assigned as the highest detected value (excluding outliers) or the highest PQL, whichever is greater.

In the case of increasing trends within the baseline period, the data will be adjusted to account for the trends where a source other than the facility can be identified and/or and alternative statistical method will be used to establish a limit. In the case of downward trends, no adjustments may be considered appropriate and a constituent-well pair may not be considered for statistical analysis until further data is collected; therefore, the trend test will serve as the alternative method for constituents with decreasing trend until the trend stabilizes.

3.2 Comparative Statistical Analysis

Comparative statistical analysis will be conducted following each detection monitoring event. For both Shewhart-CUSUM limits and non-parametric prediction limits, the comparative statistical analysis will consist of a comparison of detection monitoring results (the recent analytical results for each monitoring event performed after the baseline data period) to the statistical limit calculated from the baseline data.

The following definitions will be used in discussion of the comparative statistical analysis:

- Elevated CUSUM – an elevated CUSUM occurs when the CUSUM is greater than the Shewhart-CUSUM limit established by the baseline statistical analysis, but the analytical result does not exceed the Shewhart-CUSUM limit. An elevated CUSUM is an indication that concentrations are gradually increasing and that analytical results may exceed the Shewhart-CUSUM limit in the future.
- Potential Exceedance – is defined as an initial elevated CUSUM or an initial analytical result that exceeds the Shewhart-CUSUM limit or non-parametric statistical limit established by the baseline statistical analysis. Confirmatory resampling will determine if the potential exceedance is a false-positive or a verified statistically significant increase (SSI). Non-detect results that exceed either the Shewhart-CUSUM limit or the non-parametric statistical limit are not considered potential exceedances.

- False-positive – is defined as an analytical result that exceeds the statistical limit that can clearly be attributed to laboratory error, changes in analytical precision, or is invalidated through confirmatory re-sampling. False-positives are not used in calculation of any subsequent CUSUMs.
- Confirmatory re-sampling – is designated as the next scheduled sampling event.
- Verified SSI – is interpreted as two consecutive statistically significant increases (the original sample and the confirmatory re-sample for analytical results, or two consecutive elevated CUSUMs) for the same constituent at the same well.

The detection monitoring program has been developed to identify potential SSIs over baseline values for the Appendix III constituents. This determination will be made within 90 days of receiving the finalized laboratory analytical report(s) for each sampling event and completion of data quality review as necessary to address questions concerning the validity of sampling methods or laboratory analyses. A potential exceedance will not be considered a verified SSI until confirmatory re-sampling is performed. Confirmatory re-sampling will occur during the next regularly scheduled sampling event.

3.3 Alternative Source Demonstrations and Assessment Monitoring

If a verified SSI is identified in a downgradient well for an Appendix III constituent as part of the detection monitoring program, GRE will establish an assessment monitoring program meeting the requirements of 40 CFR 257.95 of the CCR rule. Alternatively, GRE may demonstrate that a source other than the regulated CCR facilities caused the verified SSI, or that the verified SSI was a result of an error in sampling, analysis, statistical evaluation, or natural variability in the groundwater quality that failed to be captured during baseline data collection (40 CFR 257.94(e)(2)). A report documenting the alternative source demonstration (ASD) will be certified by a Professional Engineer registered in the state of North Dakota. A copy of the report will be placed in the Site's Operating Record within 90 days of the SSI determination. If a successful demonstration is made and documented, GRE will continue with the detection monitoring program. If, after 90 days, a successful ASD is not made, GRE will initiate an assessment monitoring program as described in Section 4.0 with the first sample being collected within 90 days, per the requirements of 40 CFR 257.95.

4.0 ASSESSMENT MONITORING

An assessment monitoring program will be initiated in the event of a verified SSI of an Appendix III constituent in a downgradient well, unless a successful demonstration is made that an alternative source affected the groundwater chemistry, or that the verified SSI was a result of an error in sampling, analysis, statistical evaluation, or natural variability in the groundwater quality that was not captured during the baseline data collection period.

The statistical comparisons used in assessment monitoring require baseline analyses to be completed prior to comparative statistics. Baseline statistics for assessment monitoring mirror those for detection monitoring and are discussed in further detail in Section 2.2.

4.1 Establishment of Groundwater Protection Standards

The assessment monitoring program will comply with 40 CFR 257.95. Within 90 days of triggering the assessment monitoring program, GRE will sample and analyze each well for the Appendix IV constituents listed in Table 1. Groundwater protection standards (GWPS) will be established for each Appendix IV constituent. Per the CCR rule (40 CFR 257.95(h)), the GWPS must fall within one of the following categories:

- For constituents for which a maximum contaminant level (MCL) has been established by the USEPA (40 CFR 141.62 and 141.66), the MCL for that constituent will be the GWPS, per 40 CFR 257.95(h)(1).
- For the following constituents, the following alternative limits apply, per 40 CFR 257.95(h)(2):
  - Cobalt – 0.006 mg/L
  - Lead – 0.015 mg/L
  - Lithium – 0.04 mg/L
  - Molybdenum – 0.1 mg/L
- For constituents where the baseline level is higher than the levels identified in 40 CFR 257.91(h)(1) and 40 CFR 257.91(h)(2), the baseline level will be the GWPS per 40 CFR 257.95(h)(3).

For those constituents where the baseline level is higher than the MCL or levels designated in 40 CFR 257.91(h)(2), the GWPS will be determined through statistical methods. For those constituents with a normal or transform-normal distribution, prediction limits for future means will be developed. For constituents that are non-normal or have a high percentage of non-detects, prediction limits for future medians will be developed. For both types, the GWPS is considered a one-sided upper prediction interval calculated from the background data for specified number of future comparisons.

4.2 Comparative Statistics

To determine if Appendix IV constituents have statistically exceeded the associated GWPS, the approaches discussed in the following sections will be used.

4.2.1 Maximum Contaminant Level (MCL) and Specified Limits Based GWPS

For those constituents with MCLs and limits specified in 40 CFR 257.91(h)(2), a confidence interval approach will be used. Per recommendations provided by the Unified Guidance and detailed by EPRI (2015), a confidence interval statistically defines the upper and lower bound (the upper and lower confidence limit) of the true mean associated with a groundwater population. The Unified Guidance recommends confidence intervals for assessment monitoring. Confidence intervals identify SSIs through comparison against a fixed standard, namely the GWPS defined as the MCL or the limits specified in 40 CFR 257.91(h)(2).

To calculate a confidence interval, at least four samples (the initial sample and three resamples) are required. A confidence interval will only be considered statistically above the associated GWPS if both the upper and lower confidence limits exceed the GWPS.

4.2.2 Baseline Based GWPS

For those constituents with a GWPS based on baseline concentrations, a prediction interval approach will be used. The Unified Guidance recommends prediction intervals for a future mean for data that follow a normal or transform-normal distribution, and prediction intervals for future median for data with high percentages of non-detects or non-normally distributed data.

When using prediction intervals for a GWPS, a one-sided prediction interval is calculated using baseline datasets based on a specified number of future comparisons. For parametric comparisons, four measurements are averaged to compare to the GWPS, with statistical significance occurring when the mean is greater than the

GWPS. For non-parametric comparisons, the median of three measurements is compared to the GWPS, with statistical significance occurring when the calculated comparative median is greater than the GWPS.

4.3 Returning to Detection Monitoring, Assessment Monitoring ASD, and Assessment of Corrective Measurements

If the concentrations of constituents listed in Appendix III and Appendix IV of the rule are shown to be at or below baseline values for two consecutive sampling events, GRE will return to detection monitoring. If the concentrations of any of the Appendix III and Appendix IV constituents are above baseline values, but the Appendix IV constituents are below the established GWPS, GRE will continue with assessment monitoring. If one or more Appendix IV constituents are detected at statistically significant levels above the established GWPS, GRE will place a notification of the exceedance in the Site Operating Record and follow the course of action outlined in 40 CFR 257.95(g) of the CCR rule.

As an alternative, GRE may demonstrate that a source other than the regulated CCR facilities caused the SSI, or that the SSI was a result of an error in sampling, analysis, statistical evaluation, or natural variability int the groundwater quality that failed to be captured during baseline data collection (40 CFR 257.95(g)(3)(ii)). A report documenting the ASD will be certified by a Professional Engineer registered in the state of North Dakota. A copy of the report will be placed in the Site's Operating Record within 90 days of the SSI determination. If a successful demonstration is made and documented, the owner or operator must continue monitoring in accordance with the assessment monitoring program pursuant to 40 CFR 257.95, and may return to detection monitoring if the constituents in Appendix III and Appendix IV are at or below background. If, within 90 days, a successful ASD has not been made, GRE will initiate an assessment of corrective measures (ACM) in accordance with 40 CFR 257.96. The ACM will be completed within 90 days, unless a demonstration is made for additional time to complete the assessment. This demonstration will be certified by a Professional Engineer registered in the state of North Dakota.

5.0 REVISION HISTORY

A history of revisions to this document:

Revision 0 – Published October 12, 2017.

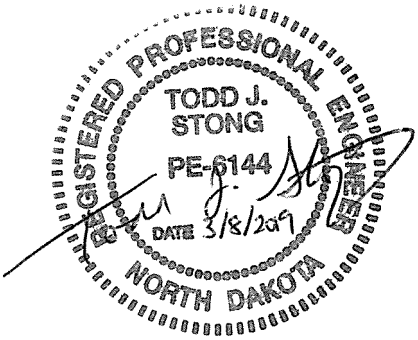
Revision 1 – Revised to reflect: Published March 8, 2019

1) Updates to the CCR rule published in the Federal Register on July 30, 2018;

2) New CCR unit naming convention (Upstream Raise to Upstream Raise 92 and Ash Pond 91 to Upstream Raise 91); and

3) Removal of calendar dates associated with the initial collection of background samples to not conflict with baseline sample collection dates for any future wells added to the program.

6.0 CERTIFICATION



Based upon the review described in this report, the undersigned certifies that the statistical methodology presented herein is appropriate for evaluating groundwater monitoring data associated with the regulated CCR facilities at CCS and meets the requirements of 40 CFR 257.93.

APPENDIX C-3

Analysis of Variance – Upgradient Wells

Sanitas™ v.9.6.27 Sanitas software licensed to Golder Associates. UG

Non-Parametric ANOVA

Constituent: Boron, Total Analysis Run 11/17/2020 9:56 AM
Coal Creek Station Client: Golder Associates Data: analytic results_CCS-CCR_Q22020

For observations made between 9/15/2015 and 4/8/2020, the non-parametric analysis of variance test indicates a DIFFERENCE between the medians of the groups tested at the 5% significance level. Because the calculated Kruskal-Wallis statistic is greater than the Chi-squared value, we conclude that at least one group has a significantly different median concentration of this constituent when compared to another group.

Calculated Kruskal-Wallis statistic = 52.39

Tabulated Chi-Squared value = 7.815 with 3 degrees of freedom at the 5% significance level.

There were 11 groups of ties in the data, consequently the Kruskal-Wallis statistic (H) was adjusted. The adjusted statistic (H') was utilized to determine if the medians were equal.
Kruskal-Wallis statistic (H) = 52.33
Adjusted Kruskal-Wallis statistic (H') = 52.39

Parametric ANOVA

Constituent: Chloride Analysis Run 11/17/2020 9:56 AM
Coal Creek Station Client: Golder Associates Data: analytic results_CCS-CCR_Q22020

For observations made between 9/15/2015 and 4/8/2020 the parametric analysis of variance test (after square root transformation) indicates VARIATION at the 5% significance level. Because the calculated F statistic is greater than the tabulated F statistic, the hypothesis of a single homogeneous population is rejected.

Calculated F statistic = 717.4

Tabulated F statistic = 2.788 with 3 and 53 degrees of freedom at the 5% significance level.

ONE-WAY PARAMETRIC ANOVA TABLE

Source of Variation	Sum of Squares	Degrees of Freedom	Mean Squares	F
Between Groups	185	3	61.68	717.4
Error Within Groups	4.556	53	0.08597	
Total	189.6	56		

The Shapiro Francia normality test on the residuals passed after square root transformation. Alpha = 0.05, calculated = 0.9621, critical = 0.961. Levene's Equality of Variance test passed. Calculated = 1.254, tabulated = 2.788.

For observations made between 9/15/2015 and 4/8/2020, the non-parametric analysis of variance test indicates a DIFFERENCE between the medians of the groups tested at the 5% significance level. Because the calculated Kruskal-Wallis statistic is greater than the Chi-squared value, we conclude that at least one group has a significantly different median concentration of this constituent when compared to another group.

Calculated Kruskal-Wallis statistic = 34.72

Tabulated Chi-Squared value = 7.815 with 3 degrees of freedom at the 5% significance level.

There were 7 groups of ties in the data, consequently the Kruskal-Wallis statistic (H) was adjusted. The adjusted statistic (H') was utilized to determine if the medians were equal.
Kruskal-Wallis statistic (H) = 30.54
Adjusted Kruskal-Wallis statistic (H') = 34.72

1.0 REPORT SUMMARY

This report presents the results from groundwater monitoring events that occurred at Great River Energy's Coal Creek Station in 2019 to meet the requirements of the Coal Combustion Residuals (CCR) rule (40 Code of Federal Regulations 257.90 through 257.98). The facilities entered 2019 under a detection monitoring program and remain in a detection monitoring program at the conclusion of 2019. The following items of statistical significance were identified in 2019 for the comparative statistical analysis of the fourth quarter (Q4) 2018 and second quarter (Q2) 2019 detection monitoring events:

- Verified Statistically Significant Increases (SSIs): No verified SSIs were identified during either the Q4 2018 or Q2 2019 detection monitoring events.
- Potential Exceedances and False-Positives:
  - The potential exceedance identified in Q2 2018 for fluoride at MW-16-6 was found to be a false-positive through confirmatory re-sampling during the Q4 2018 sampling event.
  - Four potential exceedances were identified in Q4 2018: fluoride at MW-DP5 and MW-42 and total dissolved solids (TDS) at MW-49 and MW-16-2. All four potential exceedances were determined to be false-positives through confirmatory re-sampling during the Q2 2019 sampling event.
  - Seven potential exceedances were identified in Q2 2019: chloride at MW-DP4, MW-49, MW-16-1, MW-42, and MW-72, TDS at MW-16-6, and sulfate at MW-16-1. Three of the seven potential exceedances identified were associated with upgradient wells. Confirmatory re-sampling for these samples will be completed following comparative statistical analysis for the Q4 2019 sampling event.

As described in the Coal Combustion Residuals Groundwater Monitoring System Certification, Revision 1 (Golder 2019a) and the Coal Combustion Residuals Groundwater Monitoring Statistical Methods Certification, Revision 1 (Golder 2019b), the groundwater monitoring and analytical procedures meet the general requirements of the CCR rule, and modifications to the monitoring networks and sampling program are not recommended at this time.

2.0 INTRODUCTION

Golder Associates, Inc. (Golder) has prepared this report of the 2019 groundwater sampling and comparative statistical analysis for Great River Energy's (GRE) Coal Creek Station (CCS) to meet the requirements of the Coal Combustion Residuals (CCR) rule's sections on groundwater monitoring and corrective action, 40 Code of Federal Regulations (CFR) 257.90 through 257.98.

2.1 Purpose

The CCR rule established specific requirements for reporting of actions related to groundwater monitoring and corrective actions in 40 CFR 257.90. In accordance with part (e) of 40 CFR 257.90, owners and operators of CCR units must prepare an annual groundwater monitoring and corrective action report.

2.2 Site Background

GRE's Coal Creek Station is a coal-fired electric generation facility located in McLean County, North Dakota, approximately 10 miles northwest of Washburn, North Dakota. CCRs are managed in composite-lined surface water impoundment cells and dry waste facilities regulated and permitted by the North Dakota Department of Environmental Quality (NDDEQ) in accordance with North Dakota Administrative Code Article 33-20, Solid Waste Management and Land Protection.

Coal Creek Station has four CCR facilities that are within the purview of the United States Environmental Protection Agency (USEPA) CCR rule:

- Drains Pond System CCR Surface Impoundment (Drains Pond System)
- Upstream Raise 91 CCR Surface Impoundment (Upstream Raise 91)
- Upstream Raise 92 CCR Surface Impoundment (Upstream Raise 92)
- Southeast Section 16 CCR Landfill (Southeast 16)

Each CCR facility is monitored by a separate monitoring network, in accordance with Revision 1 to the Coal Combustion Residuals Groundwater Monitoring System Certification (Golder 2019a). Locations of the facilities, groundwater monitoring network units, and groundwater monitoring wells are shown in Figure 1 and Figure 2.

3.0 GROUNDWATER MONTIORING NETWORK PROGRAM STATUS

The CCR groundwater monitoring system at CCS consists of 23 monitoring locations (eight upgradient and fifteen downgradient wells). The monitoring locations are shown in Figure 1 and 2 and listed in Table 1. Additional information on the groundwater monitoring system can be found in the Coal Combustion Residuals Groundwater Monitoring System Certification, Revision 1 (Golder 2019a). Each CCR facility is part of a monitoring network consisting of at least one upgradient and three downgradient monitoring wells.

- The Drains Pond System has two upgradient and four downgradient monitoring wells
- Upstream Raise 91 has two upgradient and three downgradient monitoring wells
- Upstream Raise 92 has two upgradient and three downgradient monitoring wells
- Southeast 16 has two upgradient and five downgradient monitoring wells

3.1 Completed Key Actions in 2019

The following key actions were completed in 2019:

- The 2018 annual CCR groundwater monitoring and corrective action report was completed and placed within the operating record and on the publicly accessible CCR website (Golder 2019c).
- Revision 1 of the Coal Combustion Residuals Groundwater Monitoring System Certification (Golder 2019a) was placed within the operating record and on the publicly accessible CCR website.
- Revision 1 of the Coal Combustion Residuals Groundwater Monitoring Statistical Methods Certification (Golder 2019b) was placed within the operating record and on the publicly accessible CCR website.
- Detection monitoring samples were collected in June (Q2) and October (Q4) 2019 at the majority of program wells and analyzed for the Appendix III constituent list associated with the CCR rule. Additionally, samples were collected from program wells for the Appendix IV constituent list associated with the CCR rule for additional baseline data.
- Comparative statistical analysis was completed for the Q4 2018 and Q2 2019 detection monitoring samples which were collected in October 2018 and June 2019, respectively, within 90 days of receipt of the final analytical results.

- Baseline statistical analysis was completed for the Appendix III constituents for MW-91-2, MW-91-1, and MW-16-0 following collection of a minimum of eight baseline samples during 2018.
- An additional Quarter 3 (Q3) 2019 sample was collected in September 2019 for Appendix III constituents as part of detection monitoring, as well as the Appendix IV constituent list for additional baseline data, for MW-91-1 and MW-91-2 (see Section 3.3 for further discussion).
- Six baseline samples were collected between June and December 2019 for well MW-DP2B, associated with the Drains Pond System, following well installation in November 2018. The December 2019 sampling analytical results have not yet been received at the time of this reporting and will be presented in the 2020 annual report. Baseline samples will continue to be collected at MW-DP2B through 2020, until a minimum of eight samples have been collected.

3.2 Installation and Decommissioning of Wells

No wells were installed or decommissioned from the CCR monitoring well networks in 2019.

3.3 Problems and Resolutions

As in 2018, no samples were able to be collected from MW-DP2 during 2019. Well MW-DP2 will continue to be monitored as part of the CCR monitoring program and samples will be collected when enough water is present within the well. Baseline samples continue to be collected at MW-DP2B (installed November 2018), which has been incorporated into the Drains Pond System monitoring program to adequately monitor the Drains Pond System.

On the laboratory reports for the Q2 2019 detection monitoring sampling event, Eurofins TestAmerica, the analytical laboratory contracted by GRE, noted that hold-time issues were encountered during analysis of chloride and sulfate. Discussions between GRE and Eurofins TestAmerica identified that the issues were primarily due to internal miscommunication at the laboratory. Each affected parameter-well pair is marked with an H qualifier on the associated results tables (Table 2 through Table 47). Further, for a subset of the analyzed samples from the Q2 2019 detection monitoring sampling event, TDS was detected in the associated method blank at a level exceeding the reporting limit. The associated sample results were not re-extracted and/or reanalyzed because the associated sample results were greater than 10 times the concentration found in the method blank. Each affected parameter-well pair is marked with a B qualifier on the associated tables (Table 2 through Table 47). The TDS values with B-qualified results are consistent with previous sampling results.

A potential issue was identified for MW-91-1 and MW-91-2 during the Q2 2019 sampling event, in which the sample bottles appear to have been switched due to a labeling error. An additional sample was collected from both MW-91-1 and MW-91-2 during Q3 2019 that confirmed a switch in samples had occurred during the Q2 2019 event. Analytical results for both the Q2 and Q3 2019 samples are shown on the sample results summary tables for informational purposes (Table 8 for MW-91-2 and Table 10 for MW-91-1), while comparative statistics have only been conducted on the Q3 results (Table 31 for MW-91-2 and Table 33 for MW-91-1).

3.4 Key Activities for 2020

The following key actions are anticipated to be completed in 2020:

- The 2019 annual CCR groundwater monitoring and corrective action report will be completed and placed within the operating record and on the publicly accessible CCR website.
- Prior to completing the comparative statistical analysis for the Q4 2019 detection monitoring sampling event, the baseline period used to establish the statistical limits for each well-parameter pair will be updated following the steps defined in Revision 1 of the Coal Combustion Residuals Groundwater Monitoring Statistical Methods Certification (Golder 2019b) and in accordance with recommendations found within the USEPA's Statistical Analysis of Groundwater Monitoring Data at RCRA Facilities Unified Guidance (USEPA 2009). Baseline periods will not be updated for well-parameter pairs where potential exceedances were identified for the Q2 2019 sampling event, as well as for locations where less than four samples have been collected since the end of their current baseline periods. Comparative statistical analysis for the Q4 2019 event will be conducted using the statistical limits from the updated baseline periods.
- Comparative statistics will be completed for the Q4 2019 detection monitoring samples within 90 days of receipt of the final analytical results.
- Detection monitoring sampling events will occur in Q2 and Q4 2020, and will consist of sampling, data review, and comparative statistics. Comparative statistics for both the Q2 2020 and Q4 2020 detection monitoring samples will be completed within 90 days of receipt of the final analytical results.
- Further baseline samples (to obtain a minimum of eight) will be collected for well MW-DP2B and will be analyzed for both the Appendix III and Appendix IV constituent list as indicated in the CCR rule.

4.0 GROUNDWATER MONITORING ANALYTICAL PROGRAM STATUS

Analytical activities associated with the groundwater monitoring program are described below.

4.1 Collected Samples

For most wells, detection monitoring samples were collected by GRE staff in June (Q2) 2019 and October (Q4) 2019. Precise dates vary between locations and can be found in Table 2 through Table 24. Six baseline samples were collected for MW-DP2B by GRE Staff between June 2019 and December 2019. Further, samples were collected for the Appendix IV constituent list for additional baseline data in Q2 2019 for wells within the CCR rule well networks. Additional samples were collected for Appendix III and Appendix IV constituents at MW-91-1 and MW-91-2 in September 2019. Results for the various samples collected throughout 2019 are summarized in Table 2 through Table 24.

Samples were collected using low-flow methodology with dedicated bladder pumps installed at each monitoring well. The sampling procedures and analytical testing methods were conducted in accordance with USEPA-accepted procedures.

4.1.1 Groundwater Elevation and Flow Rate

Depths to groundwater were measured in each well during each sampling event prior to purging. Groundwater elevations can be found in Table 2 through Table 24. Groundwater elevations and interpolated groundwater contours from the Q2 2019 detection monitoring event are shown on Figure 1. Groundwater elevations and interpolated groundwater contours form the Q4 2019 detection monitoring event are shown in Figure 2. Based on

both the Q2 (June) 2019 and Q4 (October) 2019 groundwater elevations and contours, the shallow groundwater at the CCR facilities generally follows surface topography, flowing to the east and north. The dates for groundwater information shown in the figures generally display site seasonal variability in groundwater levels between the spring/summer and fall/winter.

The groundwater flow rate across each facility was estimated with the equation $V_s = k \times i/n_e$, where:

- V_s is the groundwater flow rate, in feet per day (ft/day)
- k is the hydraulic conductivity, estimated from slug testing results from system wells, in ft/day
- i is the hydraulic gradient, calculated based on groundwater elevations for each monitoring event, in feet per feet (ft/ft)
- n_e is the effective porosity, estimated to be 0.1 for intact glacial till, which can vary from 0.06 to 0.16 and is reflective of site soils (Duffield 2007)

The range of groundwater flow rates calculated for each unit during the Q2 2019 and Q4 2019 detection monitoring sampling events are shown below. Groundwater flow rates are presented based on a range of measured hydraulic conductivity values for each unit, also shown below.

- Drains Pond (range of k values: 0.35 ft/day to 21.60 ft/day):
  - Q2 2019: 0.09 – 5.34 ft/day
  - Q4 2019: 0.08 – 5.27 ft/day
- Upstream Raise 91 (range of k values: 0.35 ft/day to 12.96 ft/day):
  - Q2 2019: 0.03 – 1.27 ft/day
  - Q4 2019: 0.03 – 1.14 ft/day
- Upstream Raise 92 (range of k values: 0.35 ft/day to 12.96 ft/day):
  - Q2 2019: 0.04 – 1.54 ft/day
  - Q4 2019: 0.04 – 1.56 ft/day
- Southeast 16 (range of k values: 1.51 ft/day to 2.59 ft/day):
  - Q2 2019: 0.02 – 0.04 ft/day
  - Q4 2019: 0.03 – 0.06 ft/day

4.2 Monitoring Data (Analytical Results)

Analytical results for samples collected in 2019 for monitoring wells within the networks are shown in Table 2 through Table 24.

4.3 Comparative Statistical Analysis

The comparative statistical analysis for the Q4 2018 and Q2 2019 detection monitoring events is summarized below, with the results presented in Table 25 through Table 47. Comparative statistical analysis for the Q4 2019 detection monitoring event will occur within 90 days of data review following receipt of the analytical data. Based on the timing of receipt of the analytical results for the Q4 2019 detection monitoring sample, comparative statistical analysis for the Q4 2019 event will be completed during the first quarter (Q1) of 2020. A full description of the steps taken for comparative statistical analyses can be found in of the Coal Combustion Residuals Groundwater Statistical Method Certification, Revision 1, Great River Energy – Coal Creek Station, available on the publicly accessible CCR website (Golder 2019b).

Comparative statistical analysis is conducted following each detection monitoring event, consisting of the Appendix III parameters (USEPA 2015). For both Shewhart-CUSUM limits and non-parametric prediction limits (NPPL), the comparative statistical analysis consists of a comparison of detection monitoring results collected during the period of interest (the compliance period) to the statistical limit calculated from the baseline period. For constituent-well pairs with increasing trends identified during the baseline period, an alternative trend test, such as that described by the Electric Power Research Institute (EPRI 2015) has been used to determine statistical significance. For constituent-well pairs with decreasing trends identified during the baseline period, a Sen's Slope trend test was used to assess the results. A detailed discussion of the methodology used for comparative statistical analysis is discussed in the Coal Combustion Residuals Groundwater Monitoring Statistical Methods Certification, Revision 1 (Golder 2019b).

4.3.1 Definitions

The following definitions will be used in discussion of the comparative statistical analysis:

- Elevated CUSUM – an elevated CUSUM occurs when the CUSUM is greater than the Shewhart-CUSUM limit established by the baseline statistical analysis, but the analytical result does not exceed the Shewhart-CUSUM limit. An elevated CUSUM is an indication that concentrations are gradually increasing and that analytical results may exceed the Shewhart-CUSUM limit in the future. For elevated CUSUMs in the case of two-tailed analysis (field-measured pH), the CUSUM value may also be below the lower Shewhart-CUSUM limit established by the baseline statistical analysis.
- Potential Exceedance – is defined as an initial elevated CUSUM or an initial analytical result that exceeds the Shewhart-CUSUM limit or non-parametric statistical limit established by the baseline statistical analysis. Confirmatory resampling will determine if the potential exceedance is a false-positive or a verified statistically significant increase (SSI). Non-detect results that exceed either the Shewhart-CUSUM limit or the non-parametric statistical limit are not considered potential exceedances.
- False-positive – is defined as an analytical result that exceeds the statistical limit that can clearly be attributed to laboratory error, changes in analytical precision, or is invalidated through confirmatory re-sampling. False-positives are not used in calculation of any subsequent CUSUMs.
- Confirmatory re-sampling – is designated as the next scheduled sampling event.
- Verified SSI – is interpreted as two consecutive exceedances (the original sample and the confirmatory re-sample for analytical results, or two consecutive elevated CUSUMs) for the same constituent at the same well.

4.3.2 Potential Exceedances

The following potential exceedances were identified during comparative statistical analysis for the Q4 2018 detection monitoring event:

- MW-DP5 (Upgradient, Drains Pond System) – Fluoride
- MW-49 (Downgradient, Upstream Raise 91) –TDS
- MW-42 (Upgradient, Southeast Section 16) – Fluoride
- MW-16-2 (Downgradient, Southeast Section 16) – TDS

Confirmatory re-sampling for these constituent-well pairs occurred during the Q2 2019 detection monitoring sampling event, with results discussed in the following sections.

The following potential exceedances were identified during comparative statistical analysis for the Q2 2019 detection monitoring event:

- MW-DP4 (Downgradient, Drains Pond System) – Chloride
- MW-49 (Downgradient, Upstream Raise 91) – Chloride Elevated CUSUM
- MW-16-6 (Upgradient, Upstream Raise 92) – TDS Elevated CUSUM
- MW-16-1 (Downgradient, Upstream Raise 92) – Sulfate Elevated CUSUM
- MW-16-1 (Downgradient, Upstream Raise 92) – Chloride Elevated CUSUM
- MW-42 (Upgradient, Southeast Section 16) – Chloride Elevated CUSUM
- MW-72 (Upgradient, Southeast Section 16) – Chloride

Confirmatory re-sampling for these constituent-well pairs occurred during the Q4 2019 detection monitoring event. Comparative statistics for the Q4 2019 detection monitoring event will be completed within 90 days of data review for the final analytical results.

4.3.3 False-Positives

The following false-positive was identified for the Q2 2018 detection monitoring event following confirmatory resampling during Q4 2018:

- MW-16-6 (Upgradient, Upstream Raise 92) – Fluoride

The following false-positives were identified for the Q4 2018 detection monitoring event following confirmatory re-sampling during Q2 2019:

- MW-DP5 (Upgradient, Drains Pond System) – Fluoride
- MW-49 (Downgradient, Upstream Raise 91) – TDS
- MW-42 (Upgradient, Southeast Section 16) – Fluoride
- MW-16-2 (Downgradient, Southeast Section 16) – TDS

4.3.4 Verified SSIs

No verified SSIs were identified during either the Q4 2018 or Q2 2019 detection monitoring events.

4.3.5 Trending Data

During establishment of baseline statistical periods, a few wells at the site were found to have trending data, preventing establishment of a statistical limit using data solely from the baseline sampling period. A description of the methods used for determining statistical significance at these wells follows.

4.3.5.1 Increasing Trends in Baseline Data

- MW-72 (Upgradient, Southeast Section 16 Facility), TDS: As an upgradient location, the facility was determined not to be the source of the increasing TDS trend at MW-72. For comparative statistics, an alternative trend test, namely that described in the EPRI guidance (2015), was used for both the Q4 2018 and Q2 2019 comparative statistics. The Q4 2018 and Q2 2019 detection monitoring data are not considered to be statistically significant. Following collection of further data, the TDS data for this location will be reassessed to determine if a baseline period can be established based on non-trending data.

4.3.5.2 Decreasing Trends in Baseline Data

- MW-91-2 (Upgradient, Upstream Raise 91), Calcium: A decreasing trend was identified during baseline statistical assessment for MW-91-2. No statistical limit was established at that time. With inclusion of the Q3 2019 result, the complete data set continues to have a statistically significant downward trend, based on Sen's Slope analysis. Following collection of further data, data for the well will be reassessed to determine if the trend continues to be present or if a baseline period can be set based on non-trending data.

5.0 PROGRAM TRANSITIONS

Beginning in Q4 2017, the groundwater monitoring programs at CCS transitioned from the baseline period to detection monitoring for the majority of program wells. During the baseline period, at least eight independent samples from each well within the program were collected and analyzed for the constituents listed in Appendix III and Appendix IV of the rule prior to October 17, 2017, as specified in 40 CFR 257.94(b). The first detection monitoring samples were collected in Q4 2017.

5.1 Detection Monitoring

The site is currently in detection monitoring. Samples for the detection monitoring program are collected on a semi-annual basis, beginning with the samples collected in Q4 2017. GRE plans to collect semi-annual samples for the detection monitoring program in Q2 and Q4 of 2020.

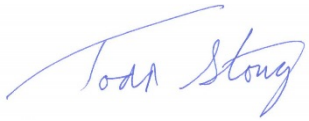
5.2 Assessment Monitoring

Results of the comparative statistical analysis through Q2 2019 at CCS do not trigger the need to implement assessment monitoring as described in 40 CFR 257.95. As such, no alternative source demonstrations have been made and there are no actions that are required as part of the assessment monitoring program.

5.3 Corrective Measures and Assessment

Results to date from the CCR groundwater monitoring program at CCS do not trigger the need to assess or implement corrective measures. Since the CCR groundwater monitoring program does not require corrective measures, an assessment of corrective measures, as described in 40 CFR 257.96, has not been initiated and no actions are required.

6.0 CLOSING



This report presents the analytical results from the Q2 2019 and Q4 2019 detection monitoring events of the CCR groundwater monitoring program at CCS. Comparative statistics for the Q4 2018 and Q2 2019 detection monitoring events are also included. Comparative statistics for the Q4 2019 detection monitoring event conducted in October 2019 will occur within 90 days of finalizing data review (during Q1 2020). The groundwater monitoring and analytical procedures implemented meet the requirements of the CCR rule and are consistent with the approach described in Revision 1 to the Groundwater Monitoring System Certification (Golder 2019a) and Revision 1 to the Groundwater Monitoring Statistical Methods Certification (Golder 2019b). Comparative statistics presented within this report support remaining in detection monitoring, and do not trigger assessment monitoring nor an assessment of corrective measures.

Notes:
TOC: top of casing
ft AMSL: feet above mean sea level
ft bgs: feet below ground surface
1. For MW-DP5, the ground surface elevation is taken from the original borehole log, but is inconsistent with the available survey for the top of casing.
2. For MW-DP1 only the top of casing elevation was provided. The PVC riser is assumed to be 2.5 ft above ground surface.
3. For MW-DP2B only the top of casing elevation was provided. The PVC riser is assumed to be 3.0 ft above ground surface.
Well construction measurements are from the original borehole log, well data sheet, or well construction form.
For some wells, elevations have been updated with more recent survey information than the original driller's logs.

pCi/L, picocuries per liter

Notes:

Non-detects have been listed at the reported practical quantitation limit.

Metal results represent the total concentration (i.e. samples have not been filtered).

Laboratory Provided Qualifiers:

U = Not detected above the shown practical quantitation limit

U (Radiochem) = Result is less than the sample detection limit (varies by sample)

^ = ICV, CCV, ICB, CCB, ISA, ISB, CRI, CRA, DLCK, or MRL standard: Instrument related QC is outside acceptance limits.

pCi/L, picocuries per liter

Notes:

Non-detects have been listed at the reported practical quantitation limit.

Metal results represent the total concentration (i.e. samples have not been filtered).

*** To date, analytical results for the December 2019 sample have not yet been received, and will be presented in the 2020 annual report.

Laboratory Provided Qualifiers:

U = Not detected above the shown practical quantitation limit

F1 = MS, MSD: The analyte present in the original sample is greater than 4 times the matrix spike concentration; therefore, control limits are not applicable.

H = Sample was prepped or analyzed beyond the specified holding time.

E = Result exceeded calibration range. Analyte was re-analyzed out of hold time with similar analytical result.

U (Radiochem) = Result is less than the sample detection limit (varies by sample)

F (Radiochem) = MS/MSD Recovery and/or RPD exceeds the control limits.

^ = ICV, CCV, ICB, CCB, ISA, ISB, CRI, CRA, DLCK, or MRL standard: Instrument related QC is outside acceptance limits.

Radium 226 and 228 combined	pCi/L	0.136 U ± 0.289	---	---
Selenium	mg/L	< 0.0050 U ^	---	---
Thallium	mg/L	< 0.0010 U	---	---

Legend:

--, not analyzed

ft AMSL, feet above mean sea level

mg/L, milligrams per liter

s.u., standard units for pH

pCi/L, picocuries per liter

Notes:

Non-detects have been listed at the reported practical quantitation limit.

Metal results represent the total concentration (i.e. samples have not been filtered).

Laboratory Provided Qualifiers:

U = Not detected above the shown practical quantitation limit

H = Sample was prepped or analyzed beyond the specified holding time, per request.

U (Radiochem) = Result is less than the sample detection limit (varies by sample)

F (Radiochem) = MS/MSD Recovery and/pr RPD exceeds the control limits.

* = LCS or LCSD is outside acceptance limits.

^ = ICV, CCV, ICB, CCB, ISA, ISB, CRI, CRA, DLCK, or MRL standard: Instrument related QC is outside acceptance limits.

1.0 INTRODUCTION

On behalf of Great River Energy (GRE), Golder Associates Inc. (Golder) performed a statistical evaluation of groundwater monitoring results from the fourth quarter (Q4) 2019 groundwater detection monitoring event at Coal Creek Station's Upstream Raise 91 coal combustion residual (CCR) surface impoundment. The statistical evaluation was performed as described in the Coal Combustion Residuals Groundwater Statistical Method Certification for Coal Creek Station, Revision 1 (Golder 2019b), in accordance with applicable provisions of 40 Code of Federal Regulations (CFR) Part 257, "Hazardous and Solid Waste Management System; Disposal of Coal Combustion Residuals from Electric Utilities; Final Rule" (CCR rule), as amended.

Statistical analyses of the Appendix III detection monitoring data for chloride in groundwater at the downgradient monitoring well MW-49 indicated a potential exceedance of the statistical limit based on the parametric Shewhart-CUSUM (Cumulative Summation) control chart analysis of the second quarter (Q2) 2019 sampling results. This potential exceedance was subsequently verified as evidence of a statistically significant increase (SSI) following the Q4 2019 detection monitoring sampling event. Although determination of a verified SSI generally indicates that the groundwater monitoring program should transition from detection monitoring to assessment monitoring, 40 CFR Part 257.94(e)(2) allows the owner or operator (i.e., GRE) 90 days from the date of determining a verified SSI (February 13, 2020) to demonstrate a source other than the regulated CCR facility caused the SSI or that the SSI was a result of an error in sampling, analysis, or statistical evaluation or natural variability in groundwater quality that was not fully captured during the baseline data collection.

Golder's review of the hydrological and geologic conditions at the site and the sampling and analytical procedures indicates the SSI is not an indication of impacts from the CCR unit. To assess potential chloride sources, including the statistical analysis and the natural variability of chloride concentrations in groundwater, a desktop study of previously collected CCR-impacted water from the facility, nearby surface water, and groundwater samples was conducted. Based upon this review and in accordance with provisions of the CCR Rule, Golder has prepared this Alternative Source Demonstration (ASD) for chloride at MW-49 and the Upstream Raise 91 CCR surface impoundment.

This ASD conforms to the requirements of 40 CFR Part 257.94(e)(2) and provides the basis for concluding that the verified SSI for chloride at MW-49 is not an indication of a release from Upstream Raise 91. The following sections provide a summary of Upstream Raise 91, sampling procedures and analytical methods, analytical and geochemical assessment results, and lines of evidence demonstrating an alternative source is responsible for the chloride SSI.

2.0 BACKGROUND

2.1 Site Background

GRE's Coal Creek Station (CCS) is a coal-fired electric generation facility located in McLean County, approximately 10 miles northwest of Washburn, North Dakota. CCRs are managed in composite-lined surface water impoundment cells and dry waste facilities regulated and permitted by the North Dakota Department of Environmental Quality (NDDEQ) in accordance with North Dakota Administrative Code (NDAC) Article 33-20, Solid Waste Management and Land Protection.

Coal Creek Station has four CCR facilities that are within the purview of the EPA CCR rule. This ASD only applies to the Upstream Raise 91 CCR surface impoundment. Upstream Raise 91 is located in the south-central portion of the plant site, east of the Coal Creek Station plant buildings (Figure 1).

2.2 Site Geology

Coal Creek Station and McLean County are situated at the eastern-most extent of the Williston Basin, a structural and sedimentary basin (USGS 1999). The region is characterized by the presence of glacial drift, reaching thicknesses of several hundred feet and overlying the Sentinel Butte Member, the source of commercially mined coal in the direct vicinity of Coal Creek Station (Falkirk 1979). The Sentinel Butte Member is the highest strata of the Paleocene Fort Union Formation, overlying the Tongue River, Ludlow, and Cannonball Members (USGS 1999). The Sentinel Butte Member is marked by drab-gray units, demarcating the separation from the lower Tongue River Member.

The site geology of CCS includes unconsolidated surficial deposits of the Coleharbor formation, consisting of stratified and unstratified glacial drift. The near-surface materials are silty clay and sandy clay till with interbedded lenses (CPA/UPA 1989).

2.3 Site Hydrogeology

Regional groundwater flow of the uppermost water-bearing unit in the vicinity of CCS is a subtle expression of the surface topography, which is influenced by the configuration of the eroded bedrock. Based on available groundwater elevation data, the shallow groundwater at the CCR facilities at Coal Creek Station generally follows surface topography, flowing east and north towards Lower Samuelson Slough and Sayler Slough. Available groundwater elevation data indicate that groundwater in the area of Upstream Raise 91 generally flows from the southwest to northeast, diagonally across the footprint of the facility, towards Lower Samuelson Slough.

Hydraulic conductivities in the area of Upstream Raise 91 range from 0.35 feet per day (ft/day) to 12.96 ft/day, with calculated groundwater flow rates during Q4 2019 ranging from 0.04 to 1.56 ft/day.

2.4 Groundwater Monitoring Network

The groundwater monitoring network for Upstream Raise 91 was developed with consideration for the size, disposal and operational history, anticipated flow direction, and location of adjoining facilities. Based on these factors, a monitoring well network consisting of two upgradient and three downgradient monitoring wells is used for monitoring the unit under the CCR rule.

The two upgradient monitoring wells (MW-75, MW-91-2) included in the groundwater monitoring network for Upstream Raise 91 are used to represent upgradient water quality flowing towards the unit from the west and south, including the potential for variability. The three downgradient wells (MW-49, MW-51, MW-91-1) are spaced along the northern edge of the facility. Upstream Raise 91 directly abuts Upstream Raise 92 on its eastern edge, preventing installation of monitoring wells along the eastern side of Upstream Raise 91 without jeopardizing the integrity of the liner system. The Upstream Raise 91 network wells are presented in Figure 1. Other monitoring locations used to support this ASD are also presented in Figure 1 and are discussed further in Section 5.0.

2.5 Groundwater Conditions

Between September 2015 and June 2017, GRE collected nine independent baseline groundwater samples from MW-75, MW-49, and MW-51, as required by 40 CFR Part 257.94, for use within the CCR rule monitoring program. Baseline samples were collected from MW-91-2 and MW-91-1 between January 2018 and October 2018, following installation of the wells in late 2017. Prior to installation of MW-91-2 and MW-91-1 and completion of the baseline monitoring at the wells, Upstream Raise 91 and Upstream Raise 92 were monitored jointly under a monitoring network consisting of the wells in both units (Golder 2019a). The results of the CCR baseline monitoring were used

to develop appropriate statistical limits for each constituent at each monitoring well, based on site and parameter specific conditions (Golder 2019b). Following completion of the baseline monitoring events at each well, GRE began collecting groundwater samples on a semi-annual basis to support the detection monitoring program. Groundwater samples for detection monitoring are collected at each upgradient and downgradient monitoring well and analyzed for 40 CFR Part 257 Appendix III constituents. During the detection monitoring program, groundwater analysis results are compared to the calculated statistical limits to determine whether groundwater quality remains consistent or if changes are noted.

Chloride concentrations in groundwater at MW-49 during the baseline monitoring period ranged between 59.2 and 67.1 milligrams per liter (mg/L) in the nine baseline samples collected as part of the CCR rule monitoring program. The Shewhart-CUSUM statistical limit for the well-constituent pair was set at 73.9 mg/L.

Following collection of the baseline monitoring events, GRE began collecting groundwater samples on a semiannual basis in October 2017 to support the detection monitoring program. Groundwater samples for detection monitoring were collected at wells within the monitoring well network and analyzed for 40 CFR Part 257 Appendix III constituents. During the detection monitoring program, results from groundwater analysis are compared to the statistical limits calculated from the baseline monitoring results to determine whether groundwater quality remains consistent, or if changes in groundwater quality are a result of statistically significant increases (SSIs) stemming from the monitored unit.

The Q2 2019 detection monitoring event reported a chloride concentration of 70.0 mg/L at MW-49, with a calculated CUSUM value of 77.4 mg/L, exceeding the statistical limit. Verification resampling was conducted during the Q4 2019 detection monitoring event, confirming the SSI for chloride at MW-49 with a chloride concentration of 71.0 mg/L and a calculated CUSUM value of 83.8 mg/L.

2.6 Sampling and Laboratory Testing Procedures

As part of the ASD, a review was conducted of the sampling and laboratory testing procedures used throughout baseline monitoring and detection monitoring to date, along with the collected results. A review of the statistical assessment methods and associated results found the procedures followed during baseline and detection monitoring to be consistent with the stated procedures listed in the published Groundwater Statistical Methods Certification (Golder 2019b). Calculated limits were found to be consistent with the chosen statistical procedures and recommended methodology found within the Unified Guidance (USEPA 2009).

In review of the analytical results a shift in the MW-49 chloride concentrations was noted between data collected prior to June 2018 and data collected after June 2018. This shift was evaluated with a Wilcoxon Rank-Sum test which showed statistical significance at the 95% confidence level (Figure 2). The Wilcoxon Rank-Sum test determines if measurements from one population are significantly different than measurements from another population. This test is non-parametric, meaning that the data are not assumed to fit a specific distribution, such as a normal distribution.

Beginning in June 2018 (Q2 2018, the second semi-annual detection monitoring event), GRE switched sampling staff. The potential impacts of this change are evaluated in Section 3.0. Also beginning in June 2018 (Q2 2018, the second semi-annual detection monitoring event), GRE switched analytical laboratories from Minnesota Valley Testing Laboratory (Bismarck, North Dakota) to Eurofins TestAmerica (Denver Laboratory in Arvada, Colorado). Concurrent with the laboratory switch, differences were noted between the testing methodologies used for chloride by the two laboratories. An evaluation of the methods and their associated differences is discussed in Section 4.1.

3.0 POTENTIAL SAMPLING CAUSES

Between September 2015 and May 2018, sampling of the CCR rule wells and other wells and surface water sampling locations at Coal Creek Station was conducted by outside contractors from the Bismarck, North Dakota location of the Minnesota Valley Testing Laboratory (MVTL). Beginning with the samples collected in June 2018, sampling has been conducted in-house by GRE employees. Low-flow pumps and sampling methods have been used to collect groundwater samples throughout the monitoring program for the CCR rule, following manufacturer recommendations (Geotech 2015) and USEPA guidance (USEPA Region I 2017). Although using the same sampling methods, there is a potential for minor differences in sampling technique between sampling personnel. The timing of the change in sampling personnel coincides with both the June 2018 shift in chloride concentrations described in Section 2.5 and the change in laboratories noted in Section 2.6.

4.0 POTENTIAL LABORATORY SOURCES

4.1 Changes in Testing Methodology

Prior to June 2018, GRE contracted MVTL as their analytical testing laboratory for the monitoring program for the CCR rule. For analysis of chloride, MVTL used a variation of the SM4500-Cl- method (published variations of the method are labeled SM4500-Cl- A through SM4500-Cl- I; Standard Methods Online 2018). In the most recent sampling prior to the analytical laboratory switch, MVTL used method SM4500-Cl- E, Chloride by Automated Ferricyanide Method. Instrumentation for the method is an automated spectrophotometer, as the method is a colorimetric means of measuring chloride in water. All variations of SM4500-Cl are only applicable for testing chloride and are not indicated for use for other analytes.

Under typical use of the method, the applicable concentration range is 1 to 200 mg/L of chloride, which can be extended to higher and lower concentrations by dilution, adjustment of sample size, and other typical testing adjustments (USGS 2002a). The typical chloride reporting limit provided by MVTL was 1.0 mg/L. Although not reported within MVTL's laboratory information management system at the time of testing, dilutions to the sample results are likely to have occurred, given the range in chloride concentrations reported using the method between 2015 and 2018 (1.1 to 697 mg/L across all CCS samples collected as part of the monitoring program for the CCR rule).

Beginning with the June 2018 sampling events for the CCR rule groundwater monitoring program, GRE contracted Eurofins TestAmerica (TestAmerica) as their analytical testing laboratory. For analysis of chloride, TestAmerica has used method SW9056A, the Determination of Inorganic Anions by Ion Chromatography (USEPA 2007). Ion chromatography identifies and separates different ions based on their affinity to an ion exchanging resin which is packed in a flow-through column. The separated ions elute off the column at different times, characteristic to the ion size and charge, and are measured using an electrical conductivity meter, generating a series of peaks as the different ions leave the column (Figure 3). Relative to a baseline level of conductivity, the area of each peak is proportional to the ion's concentration in the sample. The peak area is compared to the peak areas generated by known concentrations in calibration standards to derive a sample concentration. In the case of method SW9056A, the specified analytical column (i.e., the ion exchanger), is required to be suitable for analyzing for chloride, fluoride, bromide, nitrate, nitrite, phosphate, and sulfate.

The typical chloride reporting limit provided by TestAmerica at the Denver Laboratory was 3.0 mg/L. Dilutions have varied across samples, ranging from 1x dilution factors (i.e., no dilution and a reporting limit of 3.0 mg/L) to 50x dilution factors (with a corresponding reporting limit of 150 mg/L). Due to the capacity of the method for testing multiple anions, indiscriminate dilution intended to account for high concentrations of one anion, particularly in accounting for samples with higher sulfate concentrations as found at CCS, can negatively impact outcomes for the

other anions measured by the method, resulting in non-detect results with excessive dilutions. This aspect is particularly salient due to the base application of the method, as loading of the ion exchange column within the ion chromatograph should not exceed concentrations of approximately 500 parts per million (ppm; equivalent to 500 mg/L) of total anions within the sample when the sample to be tested is undiluted (USGS 2002b).

In comparing the methodologies used by the two laboratories, a few specific differences are apparent. First, the two methods analyze for chloride using fundamentally different mechanisms. Method SM4500-Cl^- E uses spectrophotometry, which measures how much a chemical of interest absorbs light by passing a light source through a sample. Differentiation of chemical compounds is based on the principle that each compound will absorb light over a specific range of wavelengths (Standard Methods Online 2018; USGS 2002a). Method SW9056A uses ion chromatography, quantifying the species of interest based on their affinity for an ion exchanger (USEPA 2007; USGS 2002b). Due to the difference in mechanisms between the methods, samples that are analyzed by the two methods would be anticipated to show slightly different results, even if tested portions are drawn from the same sample.

Second, larger differences between quantified results could be anticipated in samples with complex matrices, particularly those with large concentrations of other anions measured through the SW9056A methodology. Although the ion exchangers used within ion chromatography are specific to each method, the column specified by SW9056A is intended to account for the affinity of the complete list of analytes specified by the method in sequential order (USEPA 2007). In samples at CCS, concentrations of sulfate alone, as the final sequential anion within the method, often exceed the total anion loading of the methodology prior to dilution of samples. As the concentrations of chloride are less than those of sulfate within samples from CCS based on previously collected information and geochemical water-typing, masking of the intended analyte by other anions intended for quantification could skew results. Appropriate calibration across multiple concentration ranges is intended to prevent this issue. However, based on past included laboratory qualifiers and explanations within laboratory narratives, pinpointing a group of ranges across samples can prove difficult.

One further difference between the results from the two laboratories are the number of significant digits reported within sample results. Results for chloride using method SM4500-Cl^- E from MVTL were reported with 3 significant digits, while TestAmerica reports results for chloride using method SW9056A using only 2 significant digits. This difference in precision between the two laboratories may be subtle given the concentrations of chloride across samples, but could result in a difference in population medians, signifying a shift in concentrations with no cause from the facility. Similar differences are noted in the number of significant digits reported for boron, calcium, sulfate, and total dissolved solids between reporting from the two analytical laboratories.

4.2 Ion Chromatography

In addition to comparing differences between the chloride methods, Golder reviewed TestAmerica's SW9056A standard operating protocols and reviewed the ion chromatography data output data to look for practices that have the potential to bias chloride concentrations high.

The quality of ion chromatography measurements is dependent on consistently processing data in the conversion of peak area to concentration. For examples, the following aspects should be handled consistently:

- The time window used to calculate the area under a peak;
- The method for determining baseline conductivity; and
- The approach for dealing with minor peaks that elute from the column at the same time as an analyte of interest.

These data processing calculations are automatically performed by the instrument software and can result in minor differences between samples and standards. While TestAmerica checks ion chromatograph data to confirm that the instrument software is functioning consistently, there is a range of variability in the software data processing practices that is tolerated and the decision on whether to manually adjust the software-calculated concentrations by manually selecting peaks is the responsibility of TestAmerica personnel.

Golder's review of the TestAmerica ion chromatography data identified several data processing practices that have the potential to bias high chloride concentrations (Figure 4). These include:

- Using a longer integration time for samples than calibration standards;
- Selecting a lower baseline in samples relative to calibration standards; and
- Including minor shoulder peaks in sample chloride peaks when they were excluded from calibration standard chloride peaks.

These practices were implemented in the processing of the ion chromatographs for the MW-49 samples collected between 6/11/2018 and 10/16/2018 and have the potential to bias high the chloride concentrations by up to 4.2%. Golder discussed the data processing practices with TestAmerica after an internal review, and TestAmerica deemed the practices as within the range of acceptable variability and a revision to the originally reported values was not warranted (D. Bieniulis, personal communication, May 8, 2020). While up to a 4.2% difference is relatively small, this difference could account for part of the June 2018 shift in MW-49 chloride concentrations described in Section 2.5 and result in a false identification of an SSI.

5.0 POTENTIAL SITE CHLORIDE SOURCES

To assess the potential sources for a change in chloride concentrations at MW-49, Golder reviewed recent site changes upgradient of Upstream Raise 91, as well as previously collected data from the CCR rule program and other site monitoring data that are collected under other programs. The following sections summarize the supplemental assessment activities.

5.1 Site Changes and Potential Impacts

The following sections discuss site changes and potential impacts associated with those changes over the last 40 years. Site changes may have affected constituent concentrations entering the groundwater system or the hydrologic and hydrogeologic conditions (water balance) of the site.

5.1.1 Construction History and Liner System

Upstream Raise 91 was constructed on the historic footprint of the South Ash Pond, which was built in the late 1970s on a foundation of re-compacted site soils (glacial tills) and put into service in 1979. In 1981, the South Ash Pond was taken out of service to reconstruct the clay liner and was put back into service from 1982 until 1987, at which point CCR materials were removed and the geometry of the South Ash Pond footprint was modified. Monitoring wells MW-49, MW-51, and MW-75 were installed near Upstream Raise 91 in 1988 and chloride has been analyzed since that time on an approximately semi-annual basis as part of the NDDEQ monitoring program.

Chloride concentrations in MW-49 increased significantly shortly after monitoring began in the late 1980s due to likely impacts from the South Ash Pond. In 1993, Upstream Raise 91 was deepened and a new composite liner consisting of a 2-foot thick compacted clay liner underlying a 40-mil high-density polyethylene (HDPE) geomembrane was completed. Beginning in 1996, chloride concentrations started a downward trend, decreasing

by approximately 50% over the next 10-year period (approximately from a high of 170 mg/L to 85 mg/L), likely a result of construction of the composite liner system. Overall, chloride concentrations decreased approximately 60% from 1996 to 2020 (approximately from a high of 170 mg/L to 70 mg/L).

5.1.2 Duck Pond and Drains Pond System Construction

Beginning in 2015, the drainages on the west and northwest sides of Upstream Raise 91 were modified to allow for construction of an expansion to the Drains Pond System. As a part of this construction, modifications to the existing drainage upgradient of Upstream Raise 91 were required and the composite-lined west and center cells of the Drains Pond System were constructed.

Historically, the Duck Pond area was a low-lying area west of Upstream Raise 91. The depth of water contained in this area was generally 12 feet (water surface elevation approximately 1911 feet) and the Duck Pond had a surface area of approximately three acres. As the water level increased, overflow passed through culvert piping to the north under what is now the center cell of the Drains Pond System. As part of the construction in 2015, the Duck Pond was dewatered, the area was graded, and culverts were installed to drain surface water south and east around the south side of Upstream Raise 91.

5.2 Data Sources

To determine if recent site changes upgradient of Upstream Raise 91 have impacted water quality in MW-49, the sampling locations and dates for groundwater, surface water and contact water results were reviewed for each potential source provided below (see Figure 1 for locations).

5.2.1 Upstream Raise 91

Data collected between September 2015 and March 2020[1] for the CCR rule monitoring program were considered in the evaluation. As part of the monitoring program, field personnel collected groundwater samples from the following monitoring wells:

- Upgradient to Upstream Raise 91: MW-75 and MW-91-2
- Downgradient from Upstream Raise 91: MW-49, MW-51, and MW-91-1

Additionally, results for a November 2018 sample of ash contact water collected from the Upstream Raise 91 sump (Sump-UR91) were available for the evaluation.

5.2.2 Drains Pond System (East Cell)

Data collected between September 2015 and March 2020 for the CCR rule monitoring program were considered in the evaluation. As part of the monitoring program, field personnel collected groundwater samples from the following monitoring wells:

- Upgradient to the Drains Pond System: MW-DP3 and MW-DP5
- Downgradient from the Drains Pond System: MW-DP1, MW-DP2, MW-DP2B, and MW-DP4

Additionally, results for 18 samples collected between 2014 and 2019 of ash contact water collected from the surface of the east cell of the Drains Pond System (Drains Pond, SW-DP101) were used in the evaluation.

[1] June 2019 samples from MW-91-1 and MW-91-2 not used because of a suspected quality control issue

5.2.3 Upgradient Plant Cooling Water

Groundwater potentially influenced by upgradient plant cooling water is monitored at the following locations:

- Upgradient to the powerplant: MW-96
- Downgradient from the Extended Basin: MW-62, MW-63, and MW-65
- EEG Wells: MW-17-1, MW-17-2, MW-17-3, MW-17-4, and MW-17-5 (these wells were installed to monitor a leak in the fuel line to the Emergency Engine Generator)

For the plant wells, results from samples collected between October 1988 and October 2019 were considered for this evaluation. The EEG wells were installed in the fourth quarter of 2017, and results included in this evaluation were for samples collected between January 2018 and October 2019.

Additionally, results for samples collected between October 1988 and June 2019 of surface water collected from the Extended Basin (SW-107) were used in the evaluation.

5.3 Evaluation of Potential Sources

Figure 5 displays a map of the locations and observed chloride concentrations (both October 2019 concentration and the range of chloride values observed in baseline and detection monitoring) for the monitoring wells and surface water sources described in Section 5.2. As shown in Figure 1, groundwater generally flows from the west to the east. To assist with the identification of potential chloride sources to MW-49, Figure 6 compares the ranges of chloride concentrations for the monitoring wells and surface water sources on the site with a box and whisker plot. Figure 7 displays a cross plot of the sulfate to chloride ratio versus the calcium to chloride ratio as a method of comparing different water qualities across the site. Piper plots were not employed due to inconsistently having the full suite of cations and anions analytical results for the different potential chloride sources at the site.

Several potential sources can contribute chloride to local groundwater at CCS, including outflows of plant cooling water from the Extended Basin, seepage from the Drains Pond System, and seepage from Upstream Raise 91. These three potential sources of chloride to groundwater are described in this section.

5.3.1 Upstream Raise 91

The chloride concentration measured in the sample from the Upstream Raise 91 sump (790 mg/L) does indicate that seepage (if occurring) from Upstream Raise 91 could increase the chloride concentrations in MW-49. The presence of the liner system at Upstream Raise 91 (a 2-foot thick compacted clay liner with a hydraulic conductivity of $1x10^{-7}$ cm/sec or less underlying a 40-mil HDPE geomembrane) reduces the likelihood of seepage to groundwater. Figure 7 indicates that contact water in the Upstream Raise 91 sump has lower calcium to chloride ratios and lower sulfate to chloride ratios than water observed at MW-49. If seepage from Upstream Raise 91 was impacting groundwater at MW-49 a shift in both of these ratios in the most recent samples from MW-49 towards those observed in the Upstream Raise 91 sump would be expected.

5.3.2 Drains Pond

Given the physical proximity of the east cell of the Drains Pond System (Drains Pond) to MW-49 and the elevated chloride concentrations observed in the surface water of the Drains Pond (125 to 827 mg/L), seepage (if occurring) from the Drains Pond could have the potential to elevate chloride concentrations at MW-49. The presence of the liner system at the Drains Pond (a 2-foot thick compacted clay liner with a hydraulic conductivity of $1x10^{-7}$ cm/sec or less underlying a 40-mil HDPE geomembrane) reduces the likelihood of seepage to groundwater. Contact water in the

Drains Pond has lower calcium to chloride ratios than water observed in MW-49 (Figure 7). If seepage from the Drains Pond was impacting groundwater at MW-49 a shift in the calcium to chloride ratios in the most recent samples from MW-49 towards those observed in the Drains Pond would be expected.

5.3.3 Upgradient Plant Cooling Water

To the west of Upstream Raise 91 and Coal Creek Station, water used for plant cooling is stored in the Extended Basin, which holds approximately 60 million gallons and is clay lined. This water originates from the Missouri River, but is cycled up to 15 times through the cooling towers. As the water is cycled, heat from the powerplant drives evaporation, which concentrates the constituents in the Extended Basin. Between 1988 and 2019, chloride concentrations in the Extended Basin ranged between 158 and 300 mg/L.

Nearby monitoring wells (MW-62, MW-63, and MW-65) located upgradient of the powerplant and immediately adjacent to the Extended Basin also have elevated chloride concentrations ranging from 8.0 to 290 mg/L indicating that water from the Extended Basin is impacting groundwater chloride concentrations. The elevated concentrations from the Extended Basin show considerable increase relative to MW-96, a background well for the plant that is side-gradient to the Extended Basin. Chloride concentrations at MW-96 range between 4.2 and 7.8 mg/L.

The water from the Extended Basin also appears to be impacting wells further downgradient. The concentrations observed along the flow path from the Extended Basin towards MW-49 include:

- The EEG wells located east of the Extended Basin have chloride concentrations ranging from between 58 and 130 mg/L.
- Well MW-DP5 downgradient from the plant and upgradient of the Drains Pond, has chloride concentrations between 66.0 and 84.8 mg/L. Well MW-DP3 also upgradient of the Drains Pond has chloride concentrations between 8.6 and 19.8 mg/L.
- Wells MW-91-2 and MW-75 upgradient of Upstream Raise 91 and side gradient to the Extended Basin have chloride concentrations between 1.1 and 16.8 mg/L.

Variations in screened lithology and preferential flow paths in the glacial till may explain why some wells downgradient of the Extended Basin show elevated chloride concentrations while other wells (MW-DP3, MW-91-2, and MW-75) have chloride concentrations more similar to MW-96.

Figure 7 demonstrates that surface waters from the Extended Basin may be influencing ion ratios in groundwater samples from monitoring wells upgradient of Upstream Raise 91, including MW-62, MW-63, MW-65, MW-17-2, and MW-17-5, and monitoring wells downgradient of Upstream Raise 91, including MW-49 and MW-91-1.

The recent removal of the Duck Pond and regrading of the area directly upgradient of the Drains Pond potentially altered the hydrological flow paths to MW-49 and increased the proportion of water with elevated chloride from the Extended Basin monitored at MW-49. In addition to the changing flow paths, the removal of the Duck Pond also eliminated infiltration of water from the Duck Pond to groundwater, which may have provided a dilution effect to groundwater concentrations upgradient of MW-49.

6.0 EVIDENCE OF AN ALTERNATIVE SOURCE

Based on the review of sampling sources, laboratory sources and potential alternate site sources of chloride presented in this report, primary lines of evidence and conclusions drawn from the evidence used to support this ASD are provided in Table 1.

Table 1: Primary and Supporting Lines of Evidence from ASD Analysis

Key Line of Evidence	Supporting Evidence	Description
Change in Field Personnel	Changed to site personnel from MVTL	Although using the same sampling methods, there is a potential for minor differences in sampling technique between sampling personnel. The timing of the change in sampling personnel coincides with the June 2018 shift in chloride concentrations.
Change in Laboratory and Methodology	Changed to TestAmerica from MVTL	The timing of the change in laboratory coincides with the June 2018 shift in chloride concentrations.
	Change from potentiometric method (SRM 4500-CL) to ion chromatography method (SRM 9056A)	Prior to June 2018, MVTL used method SM4500-Cl- E to measure chloride concentrations. Starting in June 2018, TestAmerica analyzed chloride concentrations by SW9056A. These methods have different mechanisms, detection limits, and matrix effects. The timing of the change in methodology coincides with the June 2018 shift in chloride concentrations.
Laboratory Artifact Biasing High Sample Concentrations	Ion chromatographs reflecting different data processing practices between some calibration standards and samples	Golder's review of the TestAmerica ion chromatography data identified several data processing practices (integration time length, baseline selection, and treatment of minor peaks) that have the potential to bias high chloride concentrations (Figure 4).
Groundwater Geochemistry	Relative ion abundances in groundwater differs from Upstream Raise 91 sump water and Drains Pond surface water	The water quality signature of groundwater samples collected from downgradient well MW-49 are not consistent with the signature of potential seepage from Upstream Raise 91. As presented in the Figure 7, differences in calcium-chloride and sulfate-chloride ratios are distinctly different between the ash-impacted waters and the downgradient groundwater samples, including from MW-49.

Key Line of Evidence	Supporting Evidence	Description
Local Sources of Chloride	Elevated chloride concentrations in the Extended Basin and other wells downgradient of the Extended Basin	Figure 6 suggests that chloride concentrations in the plant cooling water (Extended Basin) are impacting groundwater chloride concentrations in wells downgradient from the Extended Basin. Similarities in the ion ratios between water samples collected from MW-49 , the Extended Basin, and wells immediately downgradient of the Extended Basin (Figure 7) suggest that the Extended Basin may be a potential source for elevated chloride at MW-49.
	Hydrogeology	The removal of the Duck Pond in 2015 and regrading of the area directly upgradient of the Drains Pond potentially altered the hydrological flow paths, resulting in higher chloride concentrations at MW-49. This would be due to an increase in the proportion of groundwater potentially impacted by the Extended Basin and the removal of the more dilute water infiltrating from the Duck Pond.

7.0 CONCLUSION

In accordance with 40 CFR 257.95(g)(3), this ASD has been prepared in response to the identification of a verified SSI for chloride at monitoring well MW-49 following the Q4 2019 sampling event for Upstream Raise 91 at Coal Creek Station.

Based on review of historical analytical results and testing procedures, recent changes to chloride concentrations in groundwater at MW-49 are likely not a result of seepage from Upstream Raise 91 but can be attributed to laboratory artifacts and variability in the upgradient groundwater sources. Therefore, no further action (i.e., a transition to Assessment Monitoring) is warranted, and Upstream Raise 91 will remain in detection monitoring.

1.0 INTRODUCTION

On behalf of Great River Energy (GRE), Golder Associates Inc. (Golder) performed a statistical evaluation of groundwater monitoring results from the second quarter (Q2) 2020 groundwater detection monitoring event at Coal Creek Station's Upstream Raise 91 coal combustion residual (CCR) surface impoundment. The statistical evaluation was performed as described in the Coal Combustion Residuals Groundwater Statistical Method Certification for Coal Creek Station, Revision 1 (Golder 2019b), in accordance with applicable provisions of 40 Code of Federal Regulations (CFR) Part 257, "Hazardous and Solid Waste Management System; Disposal of Coal Combustion Residuals from Electric Utilities; Final Rule" (CCR rule), as amended.

Statistical analyses of the Appendix III detection monitoring data for chloride in groundwater at the downgradient monitoring well MW-49 indicated a potential exceedance of the statistical limit based on the parametric Shewhart-CUSUM (Cumulative Summation) control chart analysis of the Q2 2019 sampling results. This potential exceedance was subsequently verified as a statistically significant increase (SSI) following the fourth quarter (Q4) 2019 detection monitoring sampling event. The Q2 2020 detection monitoring result for chloride at MW-49 was also a verified SSI. Although determination of a verified SSI generally indicates that the groundwater monitoring program should transition from detection monitoring to assessment monitoring, 40 CFR Part 257.94(e)(2) allows the owner or operator (i.e., GRE) 90 days from the date of determining a verified SSI (July 29, 2020) to demonstrate a source other than the regulated CCR facility caused the SSI or that the SSI was a result of an error in sampling, analysis, or statistical evaluation or natural variability in groundwater quality that was not fully captured during the baseline data collection.

Golder's review of the hydrological and geologic conditions at the site and the sampling and analytical procedures indicates the SSI is not an indication of impacts from the CCR unit. A desktop study of previously collected CCR-impacted water from the facility, nearby surface water, and groundwater samples was conducted to assess potential chloride sources. As a part of this work, potential error in the statistical analysis, laboratory methods, and the natural variability of chloride concentrations in groundwater were evaluated. Based upon this review and in accordance with provisions of the CCR Rule, Golder has prepared this Alternative Source Demonstration (ASD) for chloride at MW-49 and the Upstream Raise 91 CCR surface impoundment. An ASD was initially developed following the Q4 2019 verified SSI (Golder 2020) and was reviewed for ongoing applicability and updated where necessary.

This ASD conforms to the requirements of 40 CFR Part 257.94(e)(2) and provides the basis for concluding that the verified SSI for chloride at MW-49 is not an indication of a release from Upstream Raise 91. The following sections provide a summary of Upstream Raise 91, sampling procedures and analytical methods, analytical and geochemical assessment results, and lines of evidence demonstrating an alternative source for the increased chloride concentrations at MW-49.

2.0 BACKGROUND

2.1 Site Background

GRE's Coal Creek Station (CCS) is a coal-fired electric generation facility located in McLean County, approximately 10 miles northwest of Washburn, North Dakota. CCRs are managed in composite-lined surface water impoundment cells and dry landfills regulated and permitted by the North Dakota Department of Environmental Quality (NDDEQ) in accordance with North Dakota Administrative Code (NDAC) Article 33-20, Solid Waste Management and Land Protection.

Coal Creek Station has four CCR facilities that are within the purview of the EPA CCR rule. This ASD only applies to the Upstream Raise 91 CCR surface impoundment. Upstream Raise 91 is located in the south-central portion of the plant site, east of the Coal Creek Station plant buildings (Figure 1).

2.2 Site Geology

Coal Creek Station and McLean County are situated at the eastern-most extent of the Williston Basin, a structural and sedimentary basin (USGS 1999). The region is characterized by the presence of glacial drift, reaching thicknesses of several hundred feet and overlying the Sentinel Butte Member, the source of commercially mined coal in the direct vicinity of Coal Creek Station (Falkirk 1979). The Sentinel Butte Member is the highest strata of the Paleocene Fort Union Formation, overlying the Tongue River, Ludlow, and Cannonball Members (USGS 1999). The Sentinel Butte Member is marked by drab-gray units, demarcating the separation from the lower Tongue River Member.

The site geology of CCS includes unconsolidated surficial deposits of the Coleharbor formation, consisting of stratified and unstratified glacial drift. The near-surface materials are silty clay and sandy clay till with interbedded lenses (CPA/UPA 1989).

2.3 Site Hydrogeology

Regional groundwater flow of the uppermost water-bearing unit in the vicinity of CCS is a subtle expression of the surface topography, which is influenced by the configuration of the eroded bedrock. Based on available groundwater elevation data, the shallow groundwater at the CCR facilities at Coal Creek Station generally follows surface topography, flowing east and north towards Lower Samuelson Slough and Sayler Slough. Available groundwater elevation data indicate that groundwater in the area of Upstream Raise 91 generally flows from the southwest to northeast, diagonally across the footprint of the facility, towards Lower Samuelson Slough.

Hydraulic conductivities in the area of Upstream Raise 91 range from 0.35 feet per day (ft/day) to 12.96 ft/day, with calculated groundwater flow rates during Q2 2020 ranging from 0.03 to 1.28 ft/day.

2.4 Groundwater Monitoring Network

The groundwater monitoring network for Upstream Raise 91 was developed with consideration for the size, disposal and operational history, anticipated flow direction, and location of adjoining facilities. Based on these factors, a monitoring well network consisting of two upgradient and three downgradient monitoring wells is used for monitoring the unit under the CCR rule.

The two upgradient monitoring wells (MW-75, MW-91-2) included in the groundwater monitoring network for Upstream Raise 91 are used to represent upgradient water quality flowing towards the unit from the west and south, including the potential for variability. The three downgradient wells (MW-49, MW-51, MW-91-1) are spaced along the northern edge of the facility. Upstream Raise 91 directly abuts Upstream Raise 92 on its eastern edge, preventing installation of monitoring wells along the eastern side of Upstream Raise 91 without jeopardizing the integrity of the liner system. The Upstream Raise 91 network wells are presented in Figure 1. Other monitoring locations used to support this ASD are also presented in Figure 1 and are discussed further in Section 5.0.

2.5 Groundwater Conditions

Between September 2015 and June 2017, GRE collected nine independent baseline groundwater samples from MW-75, MW-49, and MW-51, as required by 40 CFR Part 257.94, for use within the CCR rule monitoring program. Baseline samples were collected from MW-91-2 and MW-91-1 between January 2018 and

October 2018, following installation of the wells in late 2017. Prior to installation of MW-91-2 and MW-91-1 and completion of the baseline monitoring at the wells, Upstream Raise 91 and Upstream Raise 92 were monitored jointly under a monitoring network consisting of the wells near both units (Golder 2019a). The results of the CCR baseline monitoring were used to develop appropriate statistical limits for each constituent at each monitoring well, based on site and parameter specific conditions (Golder 2019b).

Following completion of the baseline monitoring events at each well, GRE began collecting groundwater samples on a semi-annual basis to support the detection monitoring program. Groundwater samples for detection monitoring are collected at each upgradient and downgradient monitoring well and analyzed for 40 CFR Part 257 Appendix III constituents. During the detection monitoring program, results from groundwater analysis are compared to the statistical limits calculated from the baseline monitoring results to determine whether groundwater quality remains consistent, or if changes in groundwater quality are observed.

Chloride concentrations in groundwater at MW-49 during the baseline monitoring period ranged between 59.2 and 67.1 milligrams per liter (mg/L) in the nine baseline samples collected as part of the CCR rule monitoring program. The Shewhart-CUSUM statistical limit for the well-constituent pair was set at 73.9 mg/L.

The Q2 2019 detection monitoring event reported a chloride concentration of 70.0 mg/L at MW-49, with a calculated CUSUM value of 77.4 mg/L, exceeding the statistical limit. Verification resampling was conducted during the Q4 2019 detection monitoring event, confirming the SSI for chloride at MW-49 with a chloride concentration of 71.0 mg/L and a calculated CUSUM value of 83.8 mg/L. The Q2 2020 chloride result at MW-49 was also a verified SSI (based on calculated CUSUM value) with a chloride concentration of 60.0 mg/L, which is in the range of baseline values, but the calculated CUSUM value of 85.3 mg/L was greater than the statistical limit.

2.6 Sampling and Laboratory Testing Procedures

As part of the ASD, a review was conducted of the sampling and laboratory testing procedures used throughout baseline monitoring and detection monitoring to date, along with the collected results. A review of the statistical assessment methods and associated results found the procedures followed during baseline and detection monitoring to be consistent with the stated procedures listed in the published Groundwater Statistical Methods Certification (Golder 2019b). Calculated limits were found to be consistent with the chosen statistical procedures and recommended methodology found within the Unified Guidance (USEPA 2009).

In review of the analytical results, a shift in the MW-49 chloride concentrations was noted between data collected prior to June 2018 and data collected after June 2018. This shift was evaluated with a Wilcoxon Rank-Sum test which showed statistical significance at the 95% confidence level (Figure 2). The Wilcoxon Rank-Sum test determines if measurements from one population are significantly different than measurements from another population. This test is non-parametric, meaning that the data are not assumed to fit a specific distribution, such as a normal distribution.

Beginning in June 2018 (Q2 2018, the second semi-annual detection monitoring event), GRE switched sampling staff. The potential impacts of this change are evaluated in Section 3.0. Also beginning in June 2018 (Q2 2018, the second semi-annual detection monitoring event), GRE switched analytical laboratories from Minnesota Valley Testing Laboratory (Bismarck, North Dakota) to Eurofins TestAmerica (Denver Laboratory in Arvada, Colorado). There are differences between the testing methodologies used for chloride by the two laboratories. An evaluation of the methods and their associated differences is discussed in Section 4.1.

3.0 POTENTIAL SAMPLING CAUSES

Between September 2015 and May 2018, sampling of the CCR rule wells and other wells and surface water sampling locations at Coal Creek Station was conducted by outside contractors from the Bismarck, North Dakota location of the Minnesota Valley Testing Laboratory (MVTL). Beginning with the samples collected in June 2018, sampling has been conducted in-house by GRE employees. Low-flow pumps and sampling methods have been used to collect groundwater samples throughout the monitoring program for the CCR rule, following manufacturer recommendations (Geotech 2015) and USEPA guidance (USEPA Region I 2017). Although using the same sampling methods, there is a potential for minor differences in sampling technique between sampling personnel. The timing of the change in sampling personnel coincides with both the June 2018 shift in chloride concentrations described in Section 2.5 and the change in laboratories noted in Section 2.6.

4.0 POTENTIAL LABORATORY SOURCES

4.1 Changes in Testing Methodology

Prior to June 2018, GRE contracted MVTL as their analytical testing laboratory for the monitoring program for the CCR rule. For analysis of chloride, MVTL used a variation of the SM4500-Cl- method (published variations of the method are labeled SM4500-Cl- A through SM4500-Cl- I; Standard Methods Online 2018). In the most recent sampling prior to the analytical laboratory switch, MVTL used method SM4500-Cl- E, Chloride by Automated Ferricyanide Method. Instrumentation for the method is an automated spectrophotometer, as the method is a colorimetric means of measuring chloride in water. All variations of SM4500-Cl are only applicable for testing chloride and are not indicated for use for other analytes.

Under typical use of the method, the applicable concentration range is 1 to 200 mg/L of chloride, which can be extended to higher and lower concentrations by dilution, adjustment of sample size, and other typical testing adjustments (USGS 2002a). The typical chloride reporting limit provided by MVTL was 1.0 mg/L. Although not reported within MVTL's laboratory information management system at the time of testing, dilutions to the sample results are likely to have occurred, given the range in chloride concentrations reported using the method between 2015 and 2018 (1.1 to 697 mg/L across all CCS samples collected as part of the monitoring program for the CCR rule).

Beginning with the June 2018 sampling events for the CCR rule groundwater monitoring program, GRE contracted Eurofins TestAmerica (TestAmerica) as their analytical testing laboratory. For analysis of chloride, TestAmerica has used method SW9056A, the Determination of Inorganic Anions by Ion Chromatography (USEPA 2007). Ion chromatography identifies and separates different ions based on their affinity to an ion exchanging resin which is packed in a flow-through column. The separated ions elute off the column at different times, characteristic to the ion size and charge, and are measured using an electrical conductivity meter, generating a series of peaks as the different ions leave the column (Figure 3). Relative to a baseline level of conductivity, the area of each peak is proportional to the ion's concentration in the sample. The peak area is compared to the peak areas generated by known concentrations in calibration standards to derive a sample concentration. In the case of method SW9056A, the specified analytical column (i.e., the ion exchanger), is required to be suitable for analyzing for chloride, fluoride, bromide, nitrate, nitrite, phosphate, and sulfate.

The typical chloride reporting limit provided by TestAmerica at the Denver Laboratory was 3.0 mg/L. Dilutions have varied across samples, ranging from 1x dilution factors (i.e., no dilution and a reporting limit of 3.0 mg/L) to 50x dilution factors (with a corresponding reporting limit of 150 mg/L). Due to the capacity of the method for testing multiple anions, indiscriminate dilution intended to account for high concentrations of one anion,

particularly in accounting for samples with higher sulfate concentrations as found at CCS, can negatively impact outcomes for the other anions measured by the method, resulting in non-detect results with excessive dilutions. This aspect is particularly salient due to the base application of the method, as loading of the ion exchange column within the ion chromatograph should not exceed concentrations of approximately 500 parts per million ([ppm]; equivalent to 500 mg/L) of total anions within the sample when the sample to be tested is undiluted (USGS 2002b).

In comparing the methodologies used by the two laboratories, a few specific differences are apparent. First, the two methods analyze for chloride using fundamentally different mechanisms. Method SM4500-Cl- E uses spectrophotometry, which measures how much a chemical of interest absorbs light by passing a light source through a sample. Differentiation of chemical compounds is based on the principle that each compound will absorb light over a specific range of wavelengths (Standard Methods Online 2018; USGS 2002a). Method SW9056A uses ion chromatography, quantifying the species of interest based on their affinity for an ion exchanger (USEPA 2007; USGS 2002b). Due to the difference in mechanisms between the methods, samples that are analyzed by the two methods would be anticipated to show slightly different results, even if tested portions are drawn from the same sample.

Second, larger differences between quantified results could be anticipated in samples with complex matrices, particularly those with large concentrations of other anions measured through the SW9056A methodology. Although the ion exchangers used within ion chromatography are specific to each method, the column specified by SW9056A is intended to account for the affinity of the complete list of analytes specified by the method in sequential order (USEPA 2007). In samples at CCS, concentrations of sulfate alone, as the final sequential anion within the method, often exceed the total anion loading of the methodology prior to dilution of samples. As the concentrations of chloride are less than those of sulfate within samples from CCS based on previously collected information and geochemical water-typing, masking of the intended analyte by other anions intended for quantification could skew results. Appropriate calibration across multiple concentration ranges is intended to prevent this issue. However, based on past included laboratory qualifiers and explanations within laboratory narratives, pinpointing a group of ranges across samples can prove difficult.

One further difference between the results from the two laboratories are the number of significant digits reported within sample results. Results for chloride using method SM4500-Cl- E from MVTL were reported with three significant digits, while TestAmerica reports results for chloride using method SW9056A using only two significant digits. This difference in precision between the two laboratories may be subtle given the concentrations of chloride across samples, but could result in a difference in population medians, signifying a shift in concentrations with no cause from the facility. Similar differences are noted in the number of significant digits reported for boron, calcium, sulfate, and total dissolved solids between reporting from the two analytical laboratories.

4.2 Ion Chromatography

In addition to comparing differences between the chloride methods, Golder reviewed TestAmerica's SW9056A standard operating protocols and reviewed the ion chromatography data output data to look for practices that have the potential to bias chloride concentrations high.

The quality of ion chromatography measurements is dependent on consistently processing data in the conversion of peak area to concentration. For example, the following aspects should be handled consistently:

- The time window used to calculate the area under a peak,

- The method for determining baseline conductivity,
- The approach for dealing with minor peaks that elute from the column at the same time as an analyte of interest.

These data processing calculations are automatically performed by the instrument software and can result in minor differences between samples and standards. While TestAmerica checks ion chromatograph data to confirm that the instrument software is functioning consistently, there is a range of variability in the software data processing practices that is tolerated and the decision on whether to manually adjust the software-calculated concentrations by manually selecting peaks is the responsibility of TestAmerica personnel.

Golder's review of the TestAmerica ion chromatography data identified several data processing practices that have the potential to bias high chloride concentrations (Figure 4). These include:

- Using a longer integration time for samples than calibration standards,
- Selecting a lower baseline in samples relative to calibration standards, and
- Including minor shoulder peaks in sample chloride peaks when they were excluded from calibration standard chloride peaks.

These practices were implemented in the processing of the ion chromatographs for the MW-49 samples collected between June 11, 2018 and October 15, 2019 and have the potential to bias high the chloride concentrations by up to 4.2%. Golder discussed the data processing practices with TestAmerica after an internal review, and TestAmerica deemed the practices as within the range of acceptable variability and a revision to the originally reported values was not warranted (D. Bieniulis, personal communication, May 8, 2020). While up to a 4.2% difference is relatively small, this difference could account for part of the June 2018 shift in MW-49 chloride concentrations described in Section 2.5 and result in identification of an SSI.

5.0 POTENTIAL SITE CHLORIDE SOURCES

To assess the potential sources for a change in chloride concentrations at MW-49, Golder reviewed recent site changes upgradient of Upstream Raise 91, as well as previously collected data from the CCR rule program and other site monitoring data that are collected under other programs. The following sections summarize the supplemental assessment activities.

5.1 Site Changes and Potential Impacts

The following sections discuss site changes and potential impacts associated with those changes over the last 40 years. Site changes may have affected constituent concentrations entering the groundwater system or the hydrologic and hydrogeologic conditions (water balance) of the site.

5.1.1 Construction History and Liner System

Upstream Raise 91 was constructed on the historic footprint of the South Ash Pond, which was built in the late 1970s on a foundation of re-compacted site soils (glacial tills) and put into service in 1979. In 1981, the South Ash Pond was taken out of service to reconstruct the clay liner and was put back into service from 1982 until 1987, at which point CCR materials were removed and the geometry of the South Ash Pond footprint was modified. Monitoring wells MW-49, MW-51, and MW-75 were installed near Upstream Raise 91 in 1988 and chloride has been analyzed since that time on an approximately semi-annual basis as part of the NDDEQ monitoring program.

Chloride concentrations in MW-49 increased significantly shortly after monitoring began in the late 1980s due to likely impacts from the South Ash Pond. In 1993, Upstream Raise 91 was deepened and a new composite liner consisting of a 2-foot thick compacted clay liner underlying a 40-mil high-density polyethylene (HDPE) geomembrane was completed. Beginning in 1996, chloride concentrations started a downward trend, decreasing by approximately 50% over the next 10-year period (approximately from a high of 170 mg/L to 85 mg/L), likely a result of construction of the composite liner system. Overall, chloride concentrations decreased approximately 60% from 1996 to 2020 (from a high of approximately 170 mg/L to 70 mg/L).

5.1.2 Duck Pond and Drains Pond System Construction

Beginning in 2015, the drainages on the west and northwest sides of Upstream Raise 91 were modified to allow for construction of an expansion to the Drains Pond System. As a part of this construction, modifications to the existing drainage upgradient of Upstream Raise 91 were required and the composite-lined west and center cells of the Drains Pond System were constructed.

Historically, the Duck Pond area was a low-lying area west of Upstream Raise 91. The depth of water contained in this area was generally 12 feet (water surface elevation approximately 1911 feet) and the Duck Pond had a surface area of approximately three acres. As the water level increased, overflow passed through culvert piping to the north under what is now the center cell of the Drains Pond System. As part of the construction in 2015, the Duck Pond was dewatered, the area was graded, and culverts were installed to drain surface water south and east around the south side of Upstream Raise 91.

5.2 Data Sources

To determine if recent site changes upgradient of Upstream Raise 91 have impacted water quality in MW-49, the sampling locations and dates for groundwater, surface water, and contact water results were reviewed for each potential source provided below (see Figure 1 for locations).

5.2.1 Upstream Raise 91

Data collected between September 2015 and April 2020[1] for the CCR rule monitoring program were considered in the evaluation. As part of the monitoring program, field personnel collected groundwater samples from the following monitoring wells:

- Upgradient to Upstream Raise 91: MW-75 and MW-91-2
- Downgradient from Upstream Raise 91: MW-49, MW-51, and MW-91-1

Additionally, results for a November 2018 sample of ash contact water collected from the Upstream Raise 91 sump (Sump-UR91) were available for the evaluation.

5.2.2 Drains Pond System

Data collected between September 2015 and April 2020 for the CCR rule monitoring program were considered in the evaluation. As part of the monitoring program, field personnel collected groundwater samples from the following monitoring wells:

- Upgradient to the Drains Pond System: MW-DP3 and MW-DP5

[1] June 2019 samples from MW-91-1 and MW-91-2 not used because of a suspected quality control issue

- Downgradient from the Drains Pond System: MW-DP1, MW-DP2, MW-DP2B, and MW-DP4

Additionally, results for 18 samples collected between 2014 and 2019 of ash contact water collected from the surface of the east cell of the Drains Pond System (Drains Pond, SW-DP101) were used in the evaluation.

5.2.3 Upgradient Plant Cooling Water

Groundwater potentially influenced by upgradient plant cooling water is monitored at the following locations:

- Upgradient to the powerplant: MW-96
- Downgradient from the Extended Basin: MW-62, MW-63, and MW-65
- EEG Wells: MW-17-1, MW-17-2, MW-17-3, MW-17-4, and MW-17-5 (these wells were installed to monitor a historical leak in the fuel line to the Emergency Engine Generator)

For the plant wells, results from samples collected between October 1988 and April 2020 were considered for this evaluation. The EEG wells were installed in the fourth quarter of 2017, and results included in this evaluation were for samples collected between January 2018 and May 2020.

Additionally, results for samples collected between October 1988 and April 2020 of surface water collected from the Extended Basin (SW-107) were used in the evaluation.

5.3 Evaluation of Potential Sources

Figure 5 displays a map of the locations and observed chloride concentrations (both October 2019 concentration and the range of chloride values observed in baseline and detection monitoring) for the monitoring wells and surface water sources described in Section 5.2. As shown in Figure 1, groundwater generally flows from the southwest to the northeast. To assist with the identification of potential chloride sources to MW-49, Figure 6 compares the ranges of chloride concentrations for the monitoring wells and surface water sources on the site with a box and whisker plot. Figure 7 displays a scatter plot of the sulfate to chloride ratio versus the calcium to chloride ratio as a method of comparing water qualities across the site. Piper plots were not utilized due to the lack of consistently having the full suite of cations and anions for the different potential chloride sources at the site.

Several potential sources can influence chloride concentrations in groundwater at CCS, including infiltration of plant cooling water via the Extended Basin, seepage from the Drains Pond System, and seepage from Upstream Raise 91. These three potential sources of chloride are described below. The data suggests that the increase in chloride concentration at MW-49 chloride is due to a change in the hydrological flow regime caused by the 2015 removal of the Duck Pond. This change likely increased the proportion of water with elevated chloride from the Extended Basin, affecting chloride concentrations at MW-49 that resulted in the SSIs.

5.3.1 Upstream Raise 91

The chloride concentration measured in the sample from the Upstream Raise 91 sump (790 mg/L) is higher than groundwater concentrations and indicates that seepage (if occurring) from Upstream Raise 91 could increase the chloride concentrations in MW-49. The presence of the liner system at Upstream Raise 91 (a 2-foot thick compacted clay liner with a hydraulic conductivity of $1x10^{-7}$ centimeters/second or less underlying a 40-mil HDPE geomembrane) reduces the likelihood of seepage to groundwater. Figure 7 indicates that contact water in the Upstream Raise 91 sump has lower calcium to chloride ratios and lower sulfate to chloride ratios than water observed at MW-49. If seepage from Upstream Raise 91 was impacting groundwater at MW-49, a shift in both of

these ratios in samples identified as SSIs from MW-49 (Q4 2018 through Q2 2020) towards those observed from the Upstream Raise 91 sump would be expected. A shift towards the Upstream Raise 91 sump signature was not observed on Figure 7 for the samples identified as SSIs.

5.3.2 Drains Pond System

Given the physical proximity of the east cell of the Drains Pond System to MW-49 and the elevated chloride concentrations observed in the surface water of the east cell of the Drains Pond System (125 to 827 mg/L), seepage (if occurring) from the east cell of the Drains Pond System could have the potential to elevate chloride concentrations at MW-49. The presence of the liner system of the east cell of the Drains Pond System (a 2-foot thick compacted clay liner with a hydraulic conductivity of $1x10^{-7}$ centimeters/second or less underlying a 40-mil HDPE geomembrane) reduces the likelihood of seepage to groundwater. Contact water in the east cell of the Drains Pond System has lower calcium to chloride ratios than water observed in MW-49 (Figure 7). If seepage from the Drains Pond System was impacting groundwater at MW-49 a shift in the calcium to chloride ratios in the samples identified as SSIs from MW-49 (Q4 2018 through Q2 2020) towards those observed from the east cell of the Drains Pond System would be expected. A shift towards the Drains Pond System signature was not observed on Figure 7 for the samples identified as SSIs.

5.3.3 Upgradient Plant Cooling Water

To the west of Upstream Raise 91 and Coal Creek Station, water used for plant cooling is contained in the Extended Basin, which holds approximately 60 million gallons and is clay lined. The Extended Basin water originates from the Missouri River, but is cycled up to 15 times through the cooling towers. As the water is cycled, heat from the powerplant drives evaporation, which concentrates the constituents in the Extended Basin. Between 1988 and 2019, chloride concentrations in the Extended Basin ranged between 158 and 300 mg/L.

Nearby monitoring wells (MW-62, MW-63, and MW-65) located upgradient of the powerplant and immediately adjacent to the Extended Basin also have elevated chloride concentrations ranging from 8.0 to 290 mg/L indicating that water from the Extended Basin is impacting groundwater chloride concentrations. The elevated concentrations from the Extended Basin show considerable increase relative to MW-96, a background well for the plant that is side-gradient to the Extended Basin. Chloride concentrations at MW-96 range between 4.2 and 7.8 mg/L.

The water from the Extended Basin also appears to be impacting wells further downgradient. The concentrations observed along the flow path from the Extended Basin towards MW-49 include:

- The EEG wells located east of the Extended Basin have chloride concentrations ranging between 58 and 130 mg/L.
- Well MW-DP5 downgradient from the plant and upgradient of the Drains Pond System, has chloride concentrations ranging between 66.0 and 84.8 mg/L. Well MW-DP3 also upgradient of the Drains Pond has chloride concentrations ranging between 8.6 and 19.8 mg/L.
- Wells MW-91-2 and MW-75 upgradient of Upstream Raise 91 and side gradient to the Extended Basin have chloride concentrations between 1.1 and 16.8 mg/L.

Variations in screened lithology and preferential flow paths in the glacial till may explain why some wells downgradient of the Extended Basin show elevated chloride concentrations while other wells (MW-DP3, MW 91-2, and MW-75) have chloride concentrations more similar to MW-96.

Figure 7 demonstrates that surface waters from the Extended Basin may be influencing ion ratios in groundwater samples from monitoring wells upgradient of Upstream Raise 91, including MW-62, MW-63, MW-65, MW-17-2, and MW-17-5, and monitoring wells downgradient of Upstream Raise 91, including MW-49 and MW-91-1.

The recent removal of the Duck Pond and regrading of the area directly upgradient of the Drains Pond System potentially altered the hydrological flow paths to MW-49 and increased the proportion of water with elevated chloride from the Extended Basin relative to other groundwater sources monitored at MW-49. In addition to the changing flow paths, the removal of the Duck Pond also eliminated infiltration of water from the Duck Pond to groundwater, which may have provided a dilution effect on groundwater concentrations upgradient of MW-49.

6.0 EVIDENCE OF AN ALTERNATIVE SOURCE

Primary lines of evidence and conclusions drawn from the evidence used to support this ASD are provided in Table 1. In summary, the chloride SSI in MW-49 is not likely and indication of a release from Upstream Raise 91. Instead the change in chloride concentration is potentially a reflection of sampling and laboratory changes and/or changes in the groundwater flow regime related to the removal of the Duck pond that have increased the proportion of water with elevated chloride from the Extended Basin relative to other groundwater sources monitored at MW-49.

Table 1: Primary and Supporting Lines of Evidence from ASD Analysis

Key Line of Evidence	Supporting Evidence	Description
Change in Field Personnel	Changed to site personnel from MVTL	Although using the same sampling methods, there is a potential for minor differences in sampling technique between sampling personnel. The timing of the change in sampling personnel coincides with the June 2018 shift in chloride concentrations.
Change in Laboratory and Methodology	Changed to TestAmerica from MVTL	The timing of the change in laboratory coincides with the June 2018 shift in chloride concentrations.
	Change from potentiometric method (SRM 4500-CL) to ion chromatography method (SRM 9056A)	Prior to June 2018, MVTL used method SM4500-Cl- E to measure chloride concentrations. Starting in June 2018, TestAmerica analyzed chloride concentrations by SW9056A. These methods have different mechanisms, detection limits, and matrix effects. The timing of the change in methodology coincides with the June 2018 shift in chloride concentrations.
Laboratory Artifact Biasing High Sample Concentrations	Ion chromatographs reflecting different data processing practices between some calibration standards and samples	Golder's review of the TestAmerica ion chromatography data identified several data processing practices (integration time length, baseline selection, and treatment of minor peaks) that have the potential to bias high chloride concentrations (Figure 4).

Key Line of Evidence	Supporting Evidence	Description
Groundwater Geochemistry	Relative ion abundances in groundwater differs from Upstream Raise 91 sump water and surface water collected from the east cell of the Drains Pond system	The water quality signature of groundwater samples collected from downgradient well MW-49 are not consistent with the signature of potential seepage from Upstream Raise 91. As presented in the Figure 7, differences in calcium-chloride and sulfate-chloride ratios are distinctly different between the ash-impacted waters and the downgradient groundwater samples, including from MW-49.
Local Sources of Chloride	Elevated chloride concentrations in the Extended Basin and other wells downgradient of the Extended Basin	Figure 6 suggests that chloride concentrations in the plant cooling water (Extended Basin) are impacting groundwater chloride concentrations in wells downgradient from the Extended Basin. Similarities in the ion ratios between water samples collected from MW-49, the Extended Basin, and wells immediately downgradient of the Extended Basin (Figure 7) suggest that the Extended Basin may be a potential source of elevated chloride at MW-49.
	Hydrogeology	The removal of the Duck Pond in 2015 and regrading of the area directly upgradient of the Drains Pond System potentially altered the hydrological flow paths, resulting in higher chloride concentrations at MW-49. This would be due to an increase in the proportion of groundwater potentially impacted by the Extended Basin and the removal of the more dilute water infiltrating from the Duck Pond.

7.0 CONCLUSION

In accordance with 40 CFR 257.95(g)(3), this ASD has been prepared in response to the identification of a verified SSI for chloride at monitoring well MW-49 following the Q2 2020 sampling event for Upstream Raise 91 at Coal Creek Station.

Based on review of historical analytical results and testing procedures, recent changes to chloride concentrations in groundwater at MW-49 are likely not a result of seepage from Upstream Raise 91. There are two potential alternative sources, laboratory and sampling artifacts and variability in the upgradient groundwater sources. Therefore, no further action (i.e., a transition to Assessment Monitoring) is warranted, and Upstream Raise 91 will remain in detection monitoring.

LIST OF DRAWINGS

92G213 -1 through -

To verify that construction was completed in substantial compliance with the requirements of the North Dakota State Department of Health Guidelines, the following items are incorporated into this report:

* Soil test results.
* Grades of each material used during construction.
* Nuclear density test results.
* Record drawings.
* Synthetic liner field test results.
* Destructive test results.
* Material acceptance sheets.

2.0 SOURCE SAMPLING PRIOR TO CONSTRUCTION

2.1 Clay Borrow

The brown clay liner material which was used in the lower portion of the clay liner was taken from the following areas: east of EP93, north of AP91, south of AP91 and north of the Section 16 Disposal Facility. The gray clay liner material which was used in the upper portion of the clay liner and also on the sideslopes was taken from the permit K area of the Falkirk Mine and is an interburden material found in the mining operation.

All of the borrow areas were sampled and the results of preliminary tests can be found in the BET report attached. All of the tested clay samples met or exceeded the project specifications.

2.2.HDPE Conformance Samples

The 40 mil HDPE liner was sampled prior to deployment to assure that it met the specifications for the project. The results of these tests can be found in Volume I, Appendices B & D for EP93 and Appendix D for AP91 GCS report attached. All of the conformance samples met or exceeded the project specifications.

3.0 SITE EARTHWORK CONSTRUCTION

3.1 Excavation and Backfill to Subbase

The site was constructed to the grades and locations as indicated on the attached as-built drawings for the ponds.

The design of the ponds called for 1,005,000 cu. yd. of cut and 895,400 cu. yd. of fill to obtain the proper subgrade elevations as indicated on the as-built drawings. All fill material not available within the pond was borrowed from the brown clay borrow area.

The fill was hauled by scrapers and placed in 12-inch compacted lifts. Compaction to 93 percent of the standard Proctor density (ASTM D698) was achieved. Subbase soil test results are contained in the BET Report and are labeled as SG in the "Key" column.

Final subbase construction and rough surveying was facilitated by control hubs set on the base of the pond by IE. The earthwork contractor used an electronic laser positioned over the control hub to maintain the proper grade. When fine grading the subbase, a target was mounted on the blade of a Cat grader to achieve subbase grades. After the final grades were achieved, IE used a total station instrument to document the subbase grades. A 50-foot grid was used. As-built drawings show the elevations along the documentation lines.

4.0 CLAY LINER AND SIDEWALL CONSTRUCTION

4.1 General

1,240,400 cu. yd. of clay was used for the pond liner and was obtained from the borrow area as discussed earlier in Section 2.1. This lining material is referred to as brown or gray clay. 1,162,300 cu. yd. of liner-quality brown clay as used and 78,100 cu. yd. of gray clay was used from borrow areas. "Gray" clay from the Falkirk Mine was hauled to the construction area by loading coal trucks with clay. It was stockpiled and then hauled by scrapers and placed and compacted. Brown clay from the borrow areas was hauled in with scrapers by D. H. Blattner & Sons, Avon, Minnesota.

The "gray" clay in its natural state was very close to optimum moisture or just slightly wetter. The "brown" clay was also at or above optimum after being hauled and moisture conditioning for both clays was necessary at times to meet project specifications.

4.2 Construction Methods

The method of placement included spreading the clay to a depth of six to seven inches, watering the clay soil, dozing it, and watering again as required. The dozer would both level the clay lift and break down the clay clumps. An offset disc was pulled over the leveled lift, further breaking down clay clumps and breaking up the small pieces of coal in the gray clay. After the clay lift was properly conditioned, the clay layer was compacted using various compaction equipment. The majority of the clay soil was compacted using a Cat 825 self-propelled sheepsfoot compactor. Compaction was also achieved by deliberately staggered travel routes of the loaded and unloaded scrapers.

The sidewall was lined with clay. Lining a sideslope could have been accomplished by a variety of methods. However, the best method to achieve density was to place the clay in horizontal lifts. Twelve-foot wide lifts were used to allow sufficient room for the heavy equipment to operate.

The clay placement procedure for the sideslopes was as follows. Trucks and scrapers hauled the clay to the site. The clay was spread using bulldozers. Water was added as needed to keep the moisture at or above optimum. A disc was used constantly to work the added water into the soil, and to break up clay and coal clumps. Compaction was achieved with a Cat 825 self-propelled sheepsfoot compactor.

4.3 Clay Liner and Sidewall Thickness

The berms and bottom of clay liner grades were surveyed to facilitate the documentation of clay depth. When the clay liner and sidewall construction was completed, a survey of top of clay was made. For both subbase and top of clay grades, the same coordinates were used. The survey information, as presented in the as-built drawings indicates a two-foot minimum thickness of liner for the pond bottom as well as the sidewalls.

4.4 Discussion and Summary of Clay Liner Soil Testing

Based upon the specified testing frequency and the quantity and area of clay to be placed, a Construction Quality Assurance Manual (CQAM) was developed prior to construction in accordance with item i of the Solid Waste Management Permit. The CQAM was used by field soil technicians from BET, as a guide during construction. Clay liner samples on both the pond bottom and sidewalls were obtained according to the testing program.

A clay specification with the following minimum requirements for clay liner material was included in the design:

1. P200 content of 50 percent or greater.

2. Coefficient of permeability less than or equal to $1x10^{-7}$ cm/sec.

3. Liquid limit greater than or equal to 30 percent.

4. Plasticity index greater than or equal to 15 percent.

5. Compaction of 95 percent of standard Proctor density (ASTM D698) or greater.

6. Moisture content to be optimum plus 2% to optimum plus 4% compared to the optimum moisture content (ASTM D698)

The clay liner laboratory soil test results are summarized and listed in the BET Report attached.

Construction of the clay base liner and sidewall liner progressed by placing and compacting lifts of clay to a maximum compacted thickness of six inches. Four individuals lifts were required on the pond bottom and numerous lifts were required on the sideslopes to achieve a total liner thickness of two feet.

Field density tests by nuclear method were performed on an approximate 200-foot by 200-foot grid pattern for each six-inch lift of base liner. One test per each six-inch lift was also taken at a linear spacing of 200 feet on the sidewalls. An offset grid pattern system was used when testing the second six-inch lift. By this method, each lift was being tested, but not at the same coordinate location.

Moisture checks and density checks using the sand cone method (ASTM D1556) were conducted at numerous locations where nuclear method was used. This was done in order to verify the meter readings. By conducting density measurements with the use of the sand cone and moisture measurement by oven drying at the same location, we were able to determine the difference between the nuclear meter readings and actual densities (measured by the sand cone method). A moisture bias was derived as a result of these studies. The bias was then placed into the nuclear meter. The bias was checked daily by conducting several sand cones tests and moisture content measurements.

Compaction of the clay liner and sidewalls to a minimum of 95 percent of standard Proctor density was used as an in-field standard to achieve the required permeability of 1 x 10^{-7} cm/sec or less. The BET Report attached contains the density test results. Under the "Key" column, 1st lift, 2nd lift and 3rd lift are for brown clay. The 4th lift and SS (Side Slope) are for the brown and gray clay depending on the availability of gray clay.

Compaction (standard Proctor) curves were developed for the clay liner samples. The samples consisted of both "brown" and "gray" clay. The maximum densities for the "brown" clay ranged from 95 pcf to 114 pcf, while the optimum moisture contents had a range of 14 percent to 27 percent. For "gray" clay the maximum densities ranged from 98 pcf to 102 pcf and the range of the optimum moisture content was 16 percent to 24 percent. Appropriate values, based on the soil types, were used for determining the degree of compaction and for checking placement moisture specifications during construction.

659 bulk samples were collected from the borrow areas, liner and sidewalls as construction progressed. 435 shelby tube samples were also obtained for permeability testing. The soil testing completed on each Shelby tube included moisture content, unit weight, and permeability. Atterberg Limits tests and grain size analyses were performed on the bulk samples.

Approximately 2364 field density tests were taken on the subgrade, pond bottom and side slopes. Field density test results showed a range of 90% to 100%+ for the subgrade which meets the 90% specified. Field density tests for the clay liner showed a range of 95% to 100%+ which exceeds the 95% specified. All density tests which failed had the area reworked and retested.

The test results show that under the Unified Soil Classification System (U.S.C.S) "brown" clay liner is classified as a CL - Sandy Lean Clay Brown. The "gray" clay is classified as a CH - Fat Gray.

Field permeability test results from the clay showed a range in permeabilities from 1 x 10^{-7} cm/sec to 4.8 x 10^{-9} cm/sec which complies with project specifications of 1.0 x 10^{-7} cm/sec or less. The majority of the permeabilities were found to be in the 10^{-8} range, indicating a good tight liner. All failing permeability tests were retested on a second sample and if that passed then the test was assumed to be within specification. If both tests failed the area was reworked and retested.

5.0 GAS TRENCH

A trench measuring two feet wide by three feet deep was excavated around the perimeter of the site. The location of the trench is shown on the drawings. The trench was backfilled using pit-run sand gravel mixture having a permeability of 1.0 x 10^{-3} cm/sec or less. A perforated four-inch diameter PVC pipe was also placed in the trench and is shown on the drawings. Any gas which may potentially become trapped below the synthetic liner will follow the liner and enter into the trench filled with sand gravel mixture. It is further expected that the gas will then migrate through the gravel to the pipes and escape into the atmosphere.

6.0 SYNTHETIC LINER PLACEMENT

On August 5, 1992, the installation of the liner commenced in EP93 and on July 20, 1993, in AP91. The material used was a 40 mil high-density polyethylene (HDPE) geomembrane supplied and installed by Gundle Lining Systems, Inc., Houston, Texas. The Quality Assurance program as described in the project specification was monitored by GCS. The data was collected and are attached in Volumes for Geomembrane Installation attached.

6.1 Transportation, Delivery and Storage

The rolls of HDPE measured approximately 34.5 feet wide by 650 feet long and were individually wrapped for protection from the environment. The rolls were transported to the site by trucks. Upon arrival at the construction area, D. H. Blattner was responsible for the unloading of the HDPE. Each roll was logged and roll certifications verified. (Appendix C). The rolls were stored on the ground east of the construction area. They were stacked two to three rolls high. Each roll had lifting straps which remained with that roll until deployment.

6.2 Earthwork

The earthwork (clay liner) was performed by D. H. Blattner and Sons from Avon, Minnesota as described in Section 4.0. Any repairs to the clay liner were done by D. H. Blattner and Sons, as needed. Gundle issued written acceptance of the earthwork prior to placement of any HDPE. (Appendix E).

6.3 Anchor Trench

The anchor trench was excavated as needed for liner placement using a Cat grader, excavating to the line, grade and width as shown on the documentation drawings. The corners were rounded to avoid sharp bends in the geomembrane. The HDPE was placed into the trench and backfilled with compacted clay soil, as soon as possible.

6.4 Geomembrane Installation

Every sheet of HDPE bounded by four welds, or welds and the anchor trench is referred to as a panel. A total of 365 panels for AP91 and 243 panels for EP93 were placed during the lining process (Figure 1 for EP 93 and Figures 1 & 2 for AP91). A front end loader was used to haul rolls of the geomembrane from the storage area to the area of placement. The deployment of rolls was from the northwest to the southeast in EP93 and from southwest to northeast in AP91. This was done in order to take advantage of the natural slope of the pond bottom in case of rain. The membranes were inspected during the deployment for defects and/or damage. All damaged membranes were replaced. All defects, such as holes, were repaired.

The overlap of each panel was four inches. The deployed panels were pulled out and placed such that the four inches were present prior to any seaming. The four-inch overlap was the standard used for all seaming (hot shoe seam or the extrusion seam). There were no factory seams on any of the delivered rolls.

The majority of the seaming was done by a double hot shoe welder. This weld consisted of electrically heated elements which were passed between the two sheets of HDPE. Immediately following the melting, roller pressure was applied effecting a homogeneous bond. The continuous air channel formed between the two welded seams was used for pressure testing. The welding rate and the wedge temperature were monitored continuously. Appendix I, contains fusion welding summaries. Some extrusion weld seams were used and consisted of extruding at the edge of the two sheets which were welded together, keeping a four-inch overlap. The extrusion weld was also monitored for temperature. This welding method was used for repairs, corners, seams and patches. Appendix J, contains extrusion welding summaries.

Trial welds were conducted on each of the types of welds prior to construction seaming. Trial welds were conducted at the start of the work day, the early p.m., and generally after the work day. Appendix H contains all the quality assurance test data for trial welds.

6.5 Seam Testing

All seams, patches and repairs were tested by non-destructive testing. Destructive tests were performed on seams at a rate in excess of the minimum specified number.

6.5.1 Destructive Testing

The destructive test required a 48-inch long by 18-inch wide piece of HPDE with the seam centered lengthwise. The sample was cut into three pieces of equal length and distributed. The first piece was kept by Gundle. The second piece was sent to BET, who conducted shear and peel strength tests on the seam (Appendix K for EP93 and Appendix L for AP91). The third piece was archived by CPA.

A total of approximately 230 destructive test samples from AP91 and 201 from AEP93 were tested by BET. The number of samples were determined by the following considerations:

* One sample for every 500 foot of seam.

* One sample for each seamer.

* Change in weather conditions.

* Change in placement conditions (i.e., floor, toe, slope).

* Any suspect areas.

All seams from which destructive samples were taken passed the project specifications regarding shear and peel strength.

6.5.2 Non-Destructive Testing

Two methods were used during construction in order to test a seam in place. The primary method was air pressure testing, while vacuum box testing also used.

The air pressure testing method can be conducted only on a double hot shoe weld. As stated before, the double hot shoe leaves an air channel between the two shoe welds. The seam was sealed at both ends prior to testing. A needle with a pressure gauge was inserted into the air channel. Air was pumped into the air channel until the pressure gauge read at least 30 psi. This pressure was held for five minutes. If the pressure dropped 4 psi or would not stabilize, the area was retested by shortening the seam length and retesting until that length of seam passed. Repairs were then performed on the failed areas using the extrusion welder, and retested by the vacuum box method. Air test results are found in Appendix L.

The vacuum box testing methods were conducted on the extrusion welds. The extrusion welder was used for the sole purpose of seaming corners, tight areas, repairs and patches. As stated before, the extruder places extrudate while seaming.

The vacuum box is basically a rigid box with a transparent viewing window. A vacuum line from a vacuum pump powered by an electric motor is connected to the box through a gauge. The seams were prepared for tests by trimming away excess material which interfered with the seal between the box and the geomembrane. A soap-water solution was then applied to the seam. The box was placed over the wetted seam. The control valve was then energized such that 5 psi was readable on the gauge. For approximately 15 seconds, the seam was viewed for any air bubbles. If a bubble appeared, the seam was marked, repaired and retested. If the seam showed no bubbles in the viewing window, the box was moved forward to the adjacent location such that the whole length of the seam was tested. Before the box was allowed to move forward, the quality assurance inspector verified the test.

6.6 Repairs

All sample locations and damaged areas were logged and repaired. These repairs were then tested and signed off. Appendix J for EP93 and K for AP91, contain the repair summaries.

7.0 SAND BLANKET INSTALLATION

The sand blanket above the geomembrane was designed as a protective cover. The sand used for construction was processed from areas on the CCS site belonging to CPA and UPA. Gravel Products of Minot, North Dakota arrived in July of 1992 and 1993 and began screening existing soils. They screened the materials required to finish the project. They processed sand and pit-run sand gravel mixture, for the gas trench.

The sand blanket material was hauled into the pond from the processed stockpiles by trucks using a heavy equipment entrance ramp. The sand was dumped and pushed onto the geomembrane. Care was taken by the truck operators such that no damage to the geomembrane would occur.

As the sand was pushed onto the geomembrane, care was taken so that wrinkles and creases would not occur. Initial sand placement was done with a Cat dozer following the rotating laser light. Fine grading was done using a Cat grader with the same laser. Sand placement on the sideslope was done from the bottom and pushed up the slope.

The sand blanket was surveyed by IE to document the grades. As-built drawings show all the top of sand blanket grades.

Samples of the sand were analyzed for grain size and hydraulic conductivity. A total of 8 grain size analyses were conducted. The results are summarized in the BET report.

8.0 GEOTEXTILE FABRICS

Geotextile fabric was placed above the sand blanket on the pond sideslopes in EP93 and on both the sideslopes and bottom of AP91.

The non-woven fabric used on the sideslopes was Amoco style 4553. This material also arrived in approximate lengths of 400 feet long by 22 feet wide. The seams were single stitched according to the manufacturer's recommendations. The material had a 15-foot run-out at the top of berms, extending down the slope and ending at the toe. A woven geotextile was used on the bottom of AP91 manufactured by Amoco. It was placed in a manner similar to that of the non-woven.

9.0 OPERATIONAL GRADES

This section describes the additional activities conducted prior to filling.

9.1 Berm Raising

As stated in Section 3.0, the berms were leveled to the elevations shown on the plans prior to cutting for the anchor trench of the geomembrane liner. With the geomembrane liner placed and the anchor trench backfilled, sand was placed over the run-out area. A sand wedge was placed over the top of the geomembrane starting at approximately eight inches at the edge of the berm. The non-woven geotextile was then placed with clay above to secure it. Clay material was placed until the elevation was reached.

9.2 Sidewall Armor

In order to take advantage of the fly ash abundantly available at the site, the area on the dikes below the water level was covered with fly ash. The fly ash was hauled into pond bottom by CPA's ash trucks. The fly ash had water added in order to haul it to the construction area. It was end dumped at the toe of slope and pushed upward. The depth of fly ash was to be at least two feet. Care was taken in pushing the fly ash upward so as not to tear the non-woven geotextile. IE marked the elevation line on the geotextile fabric. This constant elevation was used to end the fly ash placement on the sideslopes.

At the toe of the slope a 25-foot wide by two-foot thick fly ash strip was constructed to provide increased stability of the membrane cover material on the slope. IE documented the locations of ash placement.

9.3 Riprap

DHB supplied and placed the riprap on the sideslopes. A two-foot layer was placed on the sideslopes. The constant elevation line was used for the start of riprap placement and ended at the top of the berm. The riprap was lowered into place with a backhoe moving on the top of berms. Care was taken so the non-woven fabric would not be torn.

All riprap placed was hauled in from a storage area west of AP91 or from the dikes of the abandoned recycle pond.

9.4 Bottom Ash

The final layer of material on the pond bottom was bottom ash. The purpose of this layer was for protection only, and served no other purpose. The material was hauled from ash pond 92 and placed using trucks. The material was leveled out using a Cat bulldozer and fine graded as discussed for the sand blanket placement, Section 7.0.

9.5 Drainage System

A drainage system consisting of perforated pipes leading to sump in the northeast corner was installed in AP91. This piping system was surrounded by a drainage system consisting of course rock and a fabric blanket. The purpose of the system is to allow for dewatering of the ash prior to hauling to a disposal facility.

9.6 Pond Capacity

The tables below show the capacity of the ponds for various water levels. EP93 has a maximum capacity of 221 million gallons and AP91 has a maximum capacity of 244 million gallons with 2 feet of freeboard at the operating level.

Capacity for EP93

Elev.	C.Y.	Gallons
1892	318,251	64,274,000
1893	409,008	82,603,200
1894	502,304	101,445,400
1895	597,863	120,744,000
1896	695,286	140,420,000
1897	793,627	160,281,000
1898	892,319	180,210,000
1899	987,021	199,340,000
1900	1,094,504	221,050,000

Capacity for AP91

Elev.	C.Y.	Gallons
1914	777,495	157,022,900
1915	857,643	173,209,600
1916	970,931	196,089,200
1917	1,084,216	218,968,000
1918	1,205,686	243,500,000
1919	1,314,680	265,513,000
1920	1,425,895	287,970,000

10.0 CONCLUSIONS

Based on CPA, BET and GCS observations, IE surveys, record drawings, soil test data, and geomembrane QA/QC test data, it is our opinion that the construction of Evaporation Pond 93 & Ash Pond 91 Liners has been done in substantial compliance with the Project Construction Quality Assurance Manual and the requirements of the Solid Waste Management Permit.
